Introduction, 1590
Genetic Causes of Adrenal Neoplasia, 1590
Adrenocortical Tumors, 1590
Pheochromocytoma, 1594
Summary and Future Directions, 1597

INTRODUCTION

KEY POINTS

- Hereditary and sporadic neoplasms of the adrenal cortex and medulla are characterized by a myriad of driver genetic events that alter flux through a few core cell signaling and metabolic pathways.

Primary adrenal tumors are a phenotypically heterogeneous group of diseases arising from distinct cell populations of the adrenal cortex or medulla. Disease heterogeneity also emerges from a variety of additional features, including age of onset, malignant potential, functional status (hormonally silent or active), and genetic context (sporadic or inherited). As a group, adrenal neoplasia is common in older individuals (>60 years), in whom the prevalence reaches up to 9%.[1] Most neoplasms are benign adrenocortical tumors like adrenocortical adenomas (ACA); exceedingly rare forms of adrenal neoplasia include malignant adrenocortical carcinomas (ACC), adrenal medullary pheochromocytomas (Pheo), and extraadrenal paragangliomas (PGL; often associated with inherited/syndromic Pheo).[1] Benign adrenal neoplasia also encompasses rare forms of diffuse and multinodular bilateral hyperplasia.[1] Hormonally active adrenocortical tumors can produce any class of steroid hormones or precursors, including glucocorticoids, androgens, mineralocorticoids, and estrogens. While ACA and hyperplasia usually produce a single class of steroid hormones (typically aldosterone or cortisol), ACC commonly secrete several types of steroids and precursors.[2,3] Hormonally active Pheo is also heterogeneous; epinephrine production is an exclusive feature of adrenal Pheo, norepinephrine production is more common in PGL, and elevated dopamine and production of its metabolite methoxytyramine is a feature of malignant Pheo.[4,5] In terms of the genetic context, unilateral and sporadic forms of ACA, ACC, and Pheo are more common.[6-8] However, pediatric/early-onset, bilateral, and multifocal tumors occur and are clinically suggestive of inherited forms.[6,7]

Consistent with the extraordinary clinical heterogeneity of adrenal neoplasia, the genetics of these diseases is complex. To date, approximately 20 genes are associated with inherited forms of adrenocortical neoplasia, including different types of bilateral adrenocortical hyperplasia, ACA, and ACC.[9-11] Likewise, approximately 20 genes are currently associated with inherited forms of Pheo/PGL.[7] Interestingly, these genes converge on a few signaling pathways. Genes associated with inherited adrenocortical neoplasia primarily converge on programs coordinating cell proliferation, stemness, and zone-specific hormone production. Specifically, frequently altered genes coordinate cell cycle machinery itself or signaling through IGF, Wnt/β-catenin, protein kinase A (PKA), and calcium/calmodulin signaling pathways. Genes associated with inherited Pheo/PGL primarily converge on the mitogen-activated protein kinase (MAPK) pathway, energy metabolism, and hypoxia-sensing pathways. Clinical aspects of adrenal tumor syndromes including manifestations, diagnosis, and management are discussed in other chapters.

The genetics of sporadic adrenal tumors is also complex. Candidate gene approaches revealed that genes and pathways targeted in inherited adrenal tumors are also recurrently altered in different subtypes of sporadic tumors.[9] More recently, pangenomic approaches have illuminated a spectrum of novel recurrent somatic events converging on the same signaling pathways spanned by genes associated with inherited syndromes.[12-14] Furthermore, integration of somatic alteration profiles with other "omics" such as transcriptomics, methylomics, miRnomics, and metabolomics has enabled identification of core molecular subtypes. This large array of somatic alterations has added complexity to our understanding of the molecular basis of primary adrenal tumors, while simultaneously reconciling the broad spectrum of clinical manifestations. In this chapter, we will briefly summarize the genomics of inherited and sporadic primary adrenal tumors from a pangenomic perspective.

GENETIC CAUSES OF ADRENAL NEOPLASIA

Adrenocortical Tumors

KEY POINTS

- Genetic events in benign adrenocortical neoplasia target endocrine and paracrine signaling pathways that serve to integrate homeostatic maintenance and organ function.
- Affected pathways include the Wnt/β-catenin signaling pathway, the protein kinase A pathway, and the calcium/calmodulin signaling pathway, which regulate the stem/progenitor cell compartment of the adrenal cortex, cortisol secretion in response to adrenocorticotropic hormone, and aldosterone secretion, respectively.
- Inherited and sporadic adrenocortical carcinomas possess genetic alterations in these pathways, in addition to recurrent alterations in growth factor signaling, cell cycle checkpoints, DNA mismatch-repair genes, and epigenetic regulators.

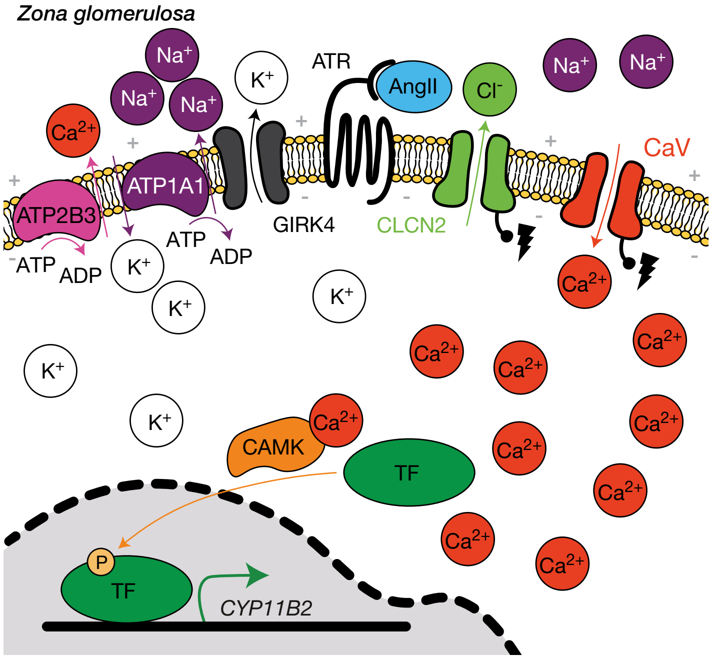

Fig. 95.1 Calcium/calmodulin signaling pathway of the adrenocortical zona glomerulosa. High levels of serum potassium and/or angiotensin II (Ang II) binding to its receptor (ATR, e.g., the receptor encoded by *AGTR1*) initiates zG membrane depolarization by inhibiting the actions of Na/K ATPase ATP1A1 and decreasing permeability of potassium channel GIRK4 (encoded by *KCNJ5*). Consequent changes in transmembrane potential trigger opening of voltage-gated chlorine channels (CLCN2) and voltage-gated calcium channels (CaV, such as those encoded by *CACNA1D* and *CACNA1H*), calcium influx and cytoplasmic accumulation, and activation of calcium/calmodulin-dependent protein kinase (CAMK). Active CAMK directly or indirectly phosphorylates and/or upregulates immediate early response transcription factors (TFs) such as the NR4A, ATF, or CREB family members, leading to transcription of aldosterone synthase (encoded by *CYP11B2*). Resting membrane potential is restored by GIRK4, ATP1A1, and calcium efflux pump ATP2B3. Inherited or somatic mutations in several components of this pathway, leading to constitutive membrane depolarization, cytoplasmic calcium accumulation, and/or transcription of *CYP11B2*, cause primary aldosteronism.

Inherited disorders associated with adrenal hyperfunction and/or overgrowth may affect the cortex or medulla. These rare diseases are typically inherited in an autosomal dominant manner and are caused by alterations in genes coordinating developmental and homeostatic pathways. Frequently altered adrenocortical signaling pathways include the Wnt/β-catenin signaling pathway, the PKA pathway, and the calcium/calmodulin signaling pathway. Disease-causing mutations in these pathways disrupt adrenocortical-specific mechanisms of integration of endocrine-paracrine signals that govern adrenal homeostasis. In addition, other pathways that are associated with broader mechanisms of tumorigenesis, including epigenetic regulation, fetal growth, and cell cycle control, are also targeted by mutations that cause adrenal cortex tumors.

Calcium/calmodulin signaling pathway: zG aldosterone production is controlled by angiotensin II (AngII) through its receptor, the angiotensin II receptor (ATR), such as the G protein-coupled receptor (GPCR) encoded by *AGTR1*. AngII binding to ATR triggers membrane depolarization, release of intracellular calcium stores, and activation of the calcium/calmodulin signaling pathway. This pathway is also activated in an ATR-independent manner, by membrane depolarization initiated by increased serum potassium. Pathway activation culminates in the rapid transcription of target genes essential for aldosterone production, including *CYP11B2*.[15-17] Germline mutations in genes that affect zG cell membrane polarization, including *CLCN2* and *KCNJ5*, and genes that regulate intracellular calcium homeostasis, including *CACNA1D* and *CACNA1H*, cause familial hyperaldosteronism type II, III, and IV and PASNA (primary aldosteronism, seizures, and neurological abnormalities). These syndromes are characterized by early-onset primary hyperaldosteronism and bilateral zG hyperplasia. Sporadic aldosterone-producing ACA bear recurrent mutations in the same classes of genes, including *KCNJ5*, *CLCN2*, *CACNA1D*, and *CACNA1H*.[10] Another class of genes recurrently mutated in sporadic aldosterone-producing ACA encode ion-transporting ATPases, including ATP1A1 and ATP2B3, also enabling constitutive zG cell membrane depolarization.[10] The aforementioned mutations are collectively present in approximately 90% of aldosterone-producing ACA.[18] This pathway is depicted in Fig. 95.1.

Wnt/β-catenin signaling pathway: The Wnt/β-catenin signaling pathway is required for adrenocortical development and homeostasis. It is a key regulator of the progenitor cell pool and shapes adrenocortical functional and anatomic zonation, presumably through tissue-specific roles.[19] The Wnt/β-catenin signaling pathway is tightly regulated by cell-autonomous and nonautonomous mechanisms (Fig. 95.2). Inactivating germline mutations in *APC,* encoding a negative regulator of β-catenin stability, causes familial adenomatous polyposis (FAP). FAP is an autosomal dominant disorder characterized by predisposition to colon cancer and other tumors such as lipomas, connective tissue sarcomas, osteomas, and bilateral adrenal tumors.[9] Subsequent studies identified somatic activating mutations in *CTNNB1*, encoding β-catenin, in up to a third of sporadic ACC and ACA, and somatic *APC* inactivation in a small subset of sporadic ACC.[9] More recently, whole-exome sequencing (WES) studies on large cohorts of ACC identified frequent (~20%) recurrent somatic biallelic deletions in *ZNRF3*, encoding an E3 membrane-bound ubiquitin ligase that also functions

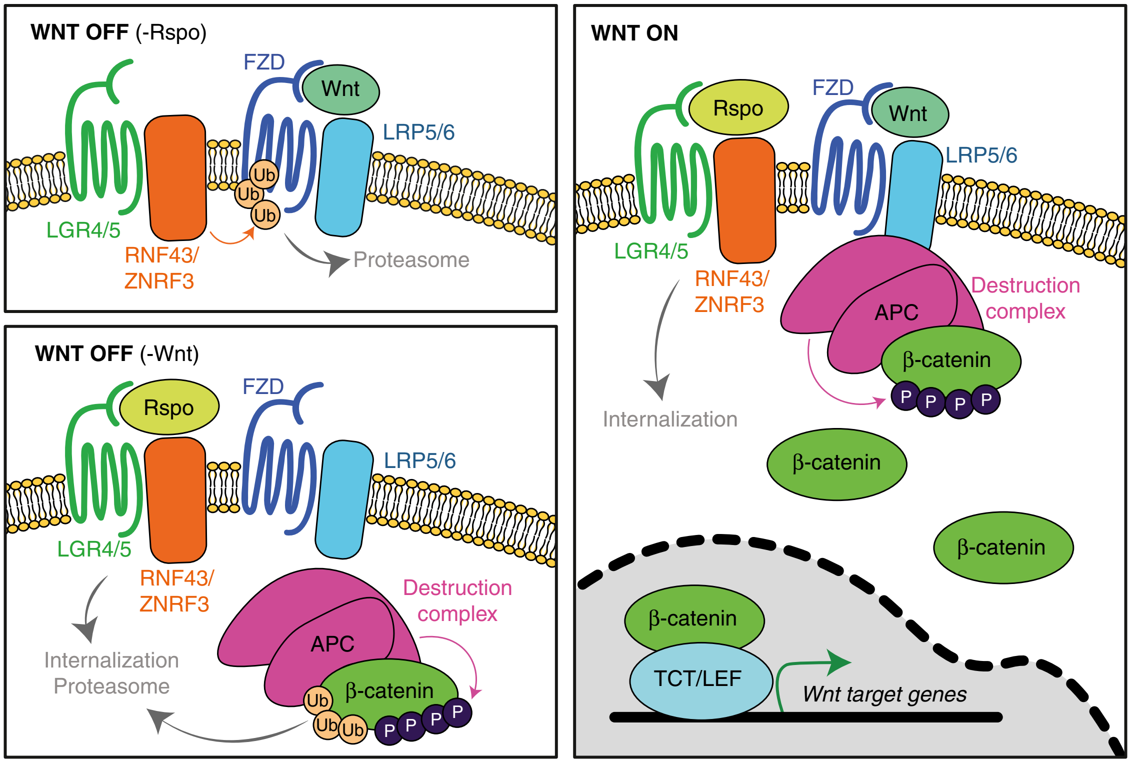

Fig. 95.2 **Wnt/β-catenin signaling pathway.** The Wnt/β-catenin signaling pathway is required for stem cell maintenance and homeostasis of a variety of organs, including the adrenal gland. The final effect of pathway activation by secreted Wnt ligands is to turn on expression of Wnt target genes through β-catenin-dependent coactivation of TCF/LEF-driven transcription. Pathway activation is controlled at several levels, primarily through regulation of stability/compartmentalization of Wnt receptors (Frizzled receptors [FZD]) and β-catenin. Membrane localization of FZDs is controlled by an additional secreted ligand, R-spondin (Rspo). Shown in the upper left ("WNT OFF (-Rspo)"), in the absence of Rspo, FZDs are targeted for degradation by membrane ubiquitin ligase RNF43 or ZNRF3. Shown in bottom left ("WNT OFF (-Wnt)"), when Rspo binds to its receptor LGR4/5, the Rspo/LGR/RNF43 or ZNRF3 complex is internalized, increasing FZD availability at the membrane. In the absence of Wnt ligands, however, β-catenin stability is regulated by a large, cytoplasmic multiprotein complex termed the "destruction complex," which includes the protein APC. In the "WNT OFF" state (as depicted bottom left), this complex binds β-catenin, phosphorylates it, and targets it for ubiquitination and proteasome-mediated destruction. Finally, when Wnt ligands bind to FZD receptors and Wnt signaling is turned on ("WNT ON," right), the destruction complex is sequestered at the cell membrane and incapable of targeting β-catenin for degradation. This allows β-catenin to accumulate in the cytoplasm and translocate to the nucleus to turn on TCF/LEF-dependent transcription. Benign and malignant adrenocortical lesions frequently harbor activating mutations in *CTNNB1*, encoding β-catenin. These mutations are often located at key residues for phosphorylation of β-catenin by the destruction complex, promoting constitutive accumulation of the protein and TCF/LEF-dependent transcription. Adrenocortical carcinomas also harbor inactivating mutations/deletions in *APC* and *ZNRF3*.

as a negative regulator of Wnt/β-catenin signaling.[12,13,20] Importantly, somatic alterations in Wnt pathway components are prevalent (nearly 40% of all ACC) and mutually exclusive, demonstrating the selective advantage conferred by constitutive Wnt/β-catenin signaling as a core driver mechanism of adrenocortical tumorigenesis.

The mechanisms by which Wnt/β-catenin signaling induces adrenocortical tumorigenesis are not fully understood. Observations from mouse models and the clinical spectrum of these tumors suggest that this mechanism is highly context-dependent. In human patients, germline *APC* mutations are associated with nonfunctional hyperplasia, and more rarely, ACA and ACC.[9] *CTNNB1* mutations are prevalent in up to 20% of adenomas and carcinomas.[9] In ACA, tumors bearing *CTNNB1* mutations are typically large and nonfunctional, exhibit mild autonomous cortisol secretion, or, rarely, exhibit aldosterone production.[21,22] In ACC, tumors bearing *CTNNB1* mutations are associated with cortisol production.[13] Pathological mutations and deletions in *ZNRF3* are exclusive to ACC. In mouse models, constitutive Wnt/β-catenin pathway activation through biallelic deletion of *Apc* or deletion of exon 3 of *Ctnnb1* leads to disrupted zonation, progressive zG hyperplasia, and coincident aldosterone overproduction.[23-25] In contrast, biallelic adrenal deletion of *Znrf3* leads to zF-like hyperplasia with massive adrenal enlargement.[26] These observations suggest constitutive Wnt/β-catenin pathway activation confers a context-dependent selective advantage to either zG or zF cells of the adrenal cortex. Combined constitutive Wnt/β-catenin pathway activation with other alterations targeting *Igf2* (encoding IGF2) or *Trp53* (encoding p53) leads to ACC and glucocorticoid excess.[23,25]

Protein kinase A: While Wnt/β-catenin signaling is an essential part of a paracrine relay that establishes and maintains the adrenocortical stem cell compartment, the PKA pathway is the effector arm of the endocrine system (adrenocorticotropic hormone [ACTH]) that induces differentiation and steroid production in the zF and zR. In

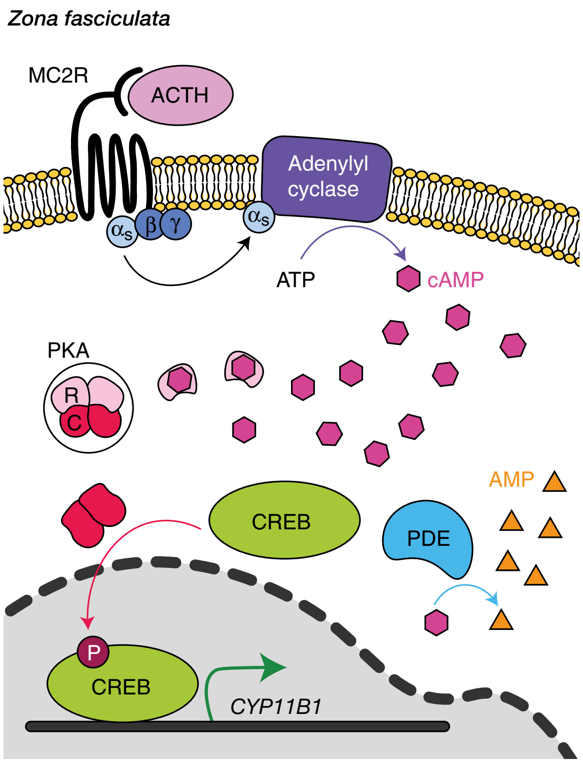

Fig. 95.3 Adrenocorticotropic hormone (ACTH)/protein kinase A (PKA) signaling pathway of the adrenocortical zona fasciculata. ACTH binds to its cell surface receptor, G protein-coupled receptor (GPCR) MC2R to activate the protein kinase A (PKA) signaling pathway. ACTH binding to MC2R triggers dissociation of the Gα,s subunit from the associated Gs protein. Gα,s binds to and activates adenylyl cyclase. Adenylyl cyclase then catalyzes the conversion of cellular ATP to cyclic AMP (cAMP). PKA is a heterotetramer, comprised of two regulatory subunits (R) and two catalytic subunits (C). cAMP binds the regulatory subunits, liberating the catalytic subunits of PKA which then catalyze phosphorylation and nuclear translocation of transcription factor CREB. CREB drives transcription of a variety of genes, including *CYP11B1*, required for glucocorticoid synthesis in the zF. Pathway activation is extinguished by intracellular phosphodiesterases (PDEs), which catalyze the conversion of cAMP to AMP, enabling reassembly of the PKA tetramer. Genetic alterations in components of this pathway leading to constitutive PKA activation and/or *CYP11B1* transcription are major causes of primary hypercortisolism in benign lesions of the adrenal cortex. Recurrent loss of function mutations in genes encoding the R subunit of PKA (e.g., *PRKAR1A*) have also been identified in adrenocortical carcinoma.

the adrenal, ACTH binding to its receptor, the GPCR MC2R, leads to cAMP accumulation and PKA activation. Catalytically active PKA in turn phosphorylates CREB family transcription factors, which translocate into the nucleus to drive expression of genes required for glucocorticoid production (e.g., *CYP11B1*). ACTH-driven PKA activation results in cell proliferation and zF differentiation with increased output of cortisol. PKA signaling is rapidly terminated by the actions of phosphodiestarases, which dephosphorylate the PKA regulatory subunits, favoring inhibitory binding to the catalytic subunit[11,27,28] (Fig. 95.3).

Several genetic syndromes presenting with adrenocortical hyperplasia and hyperfunction are caused by germline defects in genes that encode members of the PKA pathway, including *GNAS*, *PRKAR1A*, *PDE11A*, *PDE8B*, and *PRKACA*.[11] These genetic defects lead to constitutive PKA activation, rendering adrenocortical cells in a permanent state of activation characterized by cortisol overproduction and hyperplasia. Somatic mutations in PKA pathway members, including *GNAS*, *PRKACA*, *PRKAR1A*, *PRKAR1B*, and *PDE11A*, are commonly found in cortisol-producing adenomas.[29] Recurrent somatic mutations of *PRKAR1A* have been recently identified in ACC, implicating constitutive PKA signaling in malignant programming.[13]

Growth factor signaling: IGF2 is a growth factor that is widely expressed during fetal life and is one of the major regulators of intrauterine growth. Growth-promoting effects of IGF2 are mediated by the insulin-like growth factor 1 receptor (IGF1R), a receptor tyrosine kinase that activates the MAPK pathway. In physiological somatic tissues, the *IGF2* locus on 11p15.5 is imprinted and exclusively expressed by the paternal allele. The imprinting of *IGF2* is regulated by the *H19/IGF2*-imprinting control region (ICR1), located between *H19*, a long noncoding RNA with growth inhibitory functions expressed exclusively from the maternal allele, and *IGF2*. Patients with germline mutations or deletions in imprinted genes located on 11p15.5, including *CDKN1C*, *H19*, and *KCNQ1OT1*, and hypermethylation of ICR1 develop Beckwith–Wiedemann syndrome, an overgrowth disorder characterized by abdominal wall defects, abnormal growth, macroglossia, visceromegaly (including adrenocortical cytomegaly), and embryonal malignancies such as Wilms tumor, hepatoblastoma, and ACC. Interestingly, *IGF2* overexpression is present in 90% of sporadic ACC, usually associated with loss of heterozygosity (LOH) at 11p15.5 (and consequent loss of ICR1), suggesting a critical role for dysregulation of the MAPK pathway in ACC tumorigenesis.[9]

Cell cycle regulation: Germline mutations in *TP53* cause Li–Fraumeni syndrome (LFS). The prevalence of ACC in patients with LFS is approximately 5%.[30] Interestingly, the prevalence of germline *TP53* mutations among pediatric ACC cases is 50% to 90%. Somatic mutations and frequent LOH of 17p13 have often been described in sporadic ACC. The prevalence of somatic *TP53* mutations is approximately 20%. In addition to alterations in *TP53*, recurrent somatic events targeting other checkpoint regulators include inactivating mutations/deletions of *CDKN2A* and *RB1* and amplification of *CDK4* and *CCNE1*.[9,12,13,31]

DNA mismatch repair: Germline mutations in mismatch-repair genes cause Lynch syndrome. This disease is characterized by predisposition to several types of neoplasia, including gastrointestinal and gynecological tumors. Characteristically, these tumors present with microsatellite instability. ACC has also been described as part of the spectrum of Lynch syndrome.[32] Somatic mutations in mismatch-repair genes have been recently described in ACC by The Cancer Genome Atlas (TCGA), and up to 30% of ACC exhibit a mismatch repair-deficient signature, but their role in tumorigenesis is unclear.[9,33] Beyond Lynch syndrome genes, variants in other genes implicated in DNA repair, such as *MutYH*, seem to predispose to ACC, with a specific mutational signature.[34]

Other mechanisms: Germline and somatic alterations targeting other general cellular intrinsic regulatory mechanisms such as chromatin remodeling and telomere maintenance may also play a role in ACC tumorigenesis. Germline mutations in *MEN1* cause multiple endocrine neoplasia type 1 (MEN1), an autosomal dominant disorder characterized by multiple endocrine tumors, including gastrinomas, insulinomas, and parathyroid and pituitary adenomas. *MEN1* encodes menin, a protein best characterized as a scaffold protein for chromatin remodelers. Precisely how menin contributes to tissue-specific tumorigenesis is still not understood. Furthermore, up to 40% of patients with MEN1 develop nonfunctional bilateral adrenal macronodular hyperplasia that may rarely evolve to ACC.[9] Recently, recurrent somatic mutations in *MEN1* have been described in ACC, suggesting a driver role for mutations in this gene in adrenocortical carcinogenesis.[13] In addition to bearing mutations in *MEN1*, sporadic ACC may also possess alterations in genes encoding other chromatin remodeling and associated proteins, including *MLL* family members, *ATRX*, *DAXX*, *TET1*, *SETD2*, and *SMARCA4*.[12,13]

KEY POINTS

- Integrative multiplatform analyses of adrenocortical tumors have enabled the identification of distinct molecular subtypes, characterized by the coocurrence of specific molecular features such as somatic mutations targeting a given signaling pathway, activation of specific transcriptional programs, DNA methylation patterns, and chromosome copy-number alteration profiles.
- In adrenocortical carcinoma, at least three molecular subtypes have been identified, and they are strongly associate with clinical and histological metrics such as hormone secretion, mitotic counts, metastatic potential, and clinical outcomes.

Integrated molecular classification of adrenocortical adenomas: By integrating tumor genome sequencing data with gene expression (microarray, RNA-seq, and miRNA-seq), DNA methylation (Illumina arrays), chromosome alteration profiles (single nucleotide polymorphism [SNP] arrays), and proteomics, unbiased and multiplatform studies further characterized the heterogeneity of adrenal tumors and helped illuminate the molecular consequences of driver events for tumorigenesis.[12,13] Furthermore, while these studies have limited immediate translational or clinical applicability, they offer an excellent opportunity for identification of prognostic and predictive biomarkers, providing the rationale for preclinical studies directing new agents and existing targeted therapies to specific molecular subtypes.

Few studies have performed pangenomic analyses of ACA. Di Dalmazi et al.[21] performed RNA-seq in a large cohort of ACA, including samples from patients with overt Cushing syndrome, mild autonomous cortisol secretion, endocrine inactive adenomas, and low-grade low-stage ACC. Unsupervised analyses have identified three different types of ACA that presented with specific clinical and demographical features, as well as distinct somatic mutational profiles. Samples bearing somatic mutations in genes encoding PKA components including *PRKACA* and *GNAS* formed an individual cluster of tumors characterized by overt Cushing syndrome presentation, increased frequency of female sex, and smaller size. On the other hand, ACA with *CTNNB1* mutations formed another cluster of tumors characterized by mild autonomous cortisol secretion or endocrine silent tumors, older age at presentation, and no gender predilection. Finally, a small subgroup of ACA with *CTNNB1* mutations formed a cluster that exhibit transcriptional features resembling low-grade ACC. These results are consistent with other transcriptome studies of non-aldosterone-producing ACA, which identified two subtypes of tumors by unsupervised analysis that segregated cortisol-producing adenomas from those that are endocrine-silent or exhibit mild cortisol production.[22,35]

Two integrated multiplatform studies have performed molecular profiling of a large number of ACC samples.[12,13] These studies have identified discrete molecular subtypes of ACC that exhibit distinct clinical features and prognosis. De Reynies et al. identified two major transcriptional classes of ACC, C1A and C1B,[36] with striking differences in prognosis (C1A is associated with poor prognosis, and C1B is associated with good prognosis, often cured by surgical resection). Using a multiplatform approach that included microarray, methylation, microRNA-seq, SNP-array, and WES, Assie et al. expanded the characterization of the two previously identified molecular subtypes of ACC. C1A ACC exhibited a higher mutation burden, as well as frequent somatic events in driver genes, including *CTNNB1, ZNRF3, APC, TP53, RB1, CDKN2A,* and *DAXX*.[12] In addition, approximately two-thirds of C1A tumors exhibited abnormal CpG island hypermethylation (CIMP), a phenomenon previously associated with poor outcomes in ACC.[37] On the other hand, C1B exhibited a lower mutation burden, and several tumors in this class did not bear an identifiable somatic "driver." However, approximately two thirds of C1B tumors exhibited a profound deregulation of a cluster of microRNAs located in 14q32 (*DLK1-MEG3* cluster), coupled with LOH of this region, suggesting this may be the molecular event driving these tumors.

As part of the TCGA consortium, Zheng et al.[13] expanded on these studies to provide a broader multiplatform classification of ACC (ACC-TCGA). ACC-TCGA identified three unique classes of ACC (COC1, COC2, COC3), driven by differential regulation of steroidogenesis, cell cycle, and immune infiltration. Notably, each type of ACC also possessed a unique somatic copy number alteration (SCNA) profile and DNA methylation landscape. Strikingly, each molecular subtype of ACC is associated with a distinct prognostic outcome: COC1 tumors exhibited good prognosis (progression rate [PR] of 7%; median event-free survival [EFS] not reached), COC2 tumors exhibited intermediate prognosis (PR 56%; EFS 38 months), and COC3 tumors exhibited dismal prognosis (PR 96%; EFS 8 months).[13]

The vast majority of ACC is "pure," that is, free of stromal and other infiltrating immune cells, with average purity approaching 90%; however, while COC1 tumors still exhibit high purity levels in comparison to other TCGA cancers, they are characterized by low expression of steroidogenic enzymes and high expression of immune genes consistent with a higher degree of immune infiltration.[13] Like C1B tumors identified by de Reynies et al., COC1 tumors also did not possess recurrent somatic alterations. COC1 tumors had low levels of genome-wide CpG island hypermethylation (CIMP-low) and an SCNA profile termed "chromosomal," characterized by whole-chromosomal gains and losses and copy-neutral LOH, sometimes accompanied by whole-genome doubling. COC2 tumors were characterized by largely absent immune infiltration, high expression of steroidogenic enzymes, and recurrent somatic alterations targeting the Wnt/β-catenin pathway. COC2 ACC had intermediate levels of genome-wide CpG island hypermethylation (CIMP-intermediate) and a chromosomal SCNA profile. Finally, COC3 tumors were characterized by largely absent immune infiltration, high expression of steroidogenic enzymes and cell cycle machinery, and recurrent somatic alterations targeting the Wnt/β-catenin pathway and cell cycle. COC3 tumors had high levels of genome-wide CpG island hypermethylation (CIMP-high) and a SCNA profile termed "noisy," characterized by focal arm-level gains and losses and numerous breakpoints, sometimes accompanied by whole-genome doubling (Fig. 95.4).

The completion of ACC-TCGA enabled incorporation of ACC into larger pancancer pangenomic datasets. These studies have identified several unique characteristics of ACC, with therapeutic implications. Up to a third of ACC exhibit a somatic mismatch repair-deficient signature,[33] and most ACC is immune-poor, with minimal lymphocyte infiltration,[38] suggesting these tumors are as a majority resistant to immunotherapy, consistent with recent clinical studies.[39] On an epigenetic level, the accessible chromatin landscape of ACC is largely dominated by the adrenocortical transcription factor SF1,[40] suggesting that potentially efficacious epigenetic therapies would need to unwire this highly tissue-specific program.

Pheochromocytoma

Up to 40% of Pheo/PGL are associated with inherited syndromes, and to date there are approximately 20 well-documented susceptibility genes.[7] Clinical aspects of these syndromes and strategies for genetic testing and clinical management are beyond the scope of this chapter and are discussed elsewhere. Broadly, two signaling pathways are most affected by these germline mutations: cellular hypoxia and activated kinase signaling.[41,42] Activation of the cellular hypoxia pathway

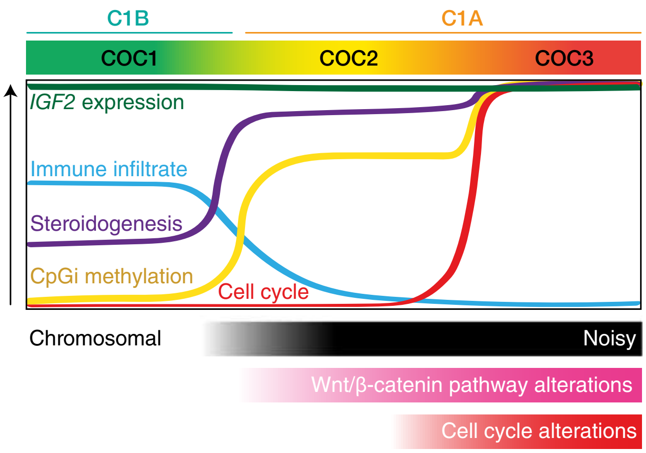

Fig. 95.4 **Molecular subtyping of adrenocortical carcinoma (ACC).** Recent pangenomic studies (namely, The Cancer Genome Atlas study on ACC [ACC-TCGA]) have revealed that ACC is comprised of three distinct molecular subtypes, COC1, COC2, and COC3. Not shown in this figure, each subtype is associated with a unique clinical outcome where patients with COC1 tumors have the best outcomes (longer progression-free survival), patients with COC2 tumors have intermediate outcomes, and patients with COC3 tumors have the worst outcomes (shortened progression-free survival with near uniform likelihood of relapse within 2 years). Strikingly, ACC-TCGA revealed that each class of tumors is defined by a combination of core transcriptional programs, DNA methylation profiles, and somatic alterations. All ACC possess high levels of *IGF2* expression, secondary to loss of imprinting of this locus. COC1 tumors possess the lowest expression of steroidogenic enzymes, the lowest degree of cell cycle activation, the lowest levels of promoter CpG island (CpGi) methylation (CIMP-low), and few to no recurrent somatic alterations. COC1 tumors bear a somatic copy number alteration profile characterized by whole arm/whole chromosome loss of heterozygosity (LOH), called "chromosomal." COC1 tumors also possess a moderate degree of immune infiltration (approaching 50% in some tumors). In contrast, COC2 and COC3 tumors bear high expression of steroidogenic enzymes, higher levels of CpGi methylation (CIMP-intermediate and CIMP-high), and frequent Wnt/β-catenin pathway alterations. These tumors are also characterized by a low to near-absent immune infiltration. COC3 tumors possess the highest expression of steroidogenic enzymes, highest degree of cell cycle activation, and highest degree of CpGi methylation (CIMP-high). In contrast to COC1–2 tumors, COC3 possess a "noisy" somatic copy number alteration profile, characterized by numerous focal arm-level copy number gains and losses throughout the genome. Finally, as shown at the top of the plot, the transcriptional programs driving COC1 and COC2–3 tumors resemble the C1B and C1A signatures originally identified by de Reynies et al. in a seminal unbiased study using microarray to characterize transcriptional programs driving adrenocortical tumors.

is driven by the hypoxia-inducible factor (HIF) family of transcription factors. Physiologically, this pathway is activated in response to cellular hypoxia, a state that is recognized by hypoxia-sensing proteins, which trigger a downstream signaling cascade that leads to the accumulation of HIF family members. HIF induces the expression of a broad spectrum of genes that promote erythropoiesis, angiogenesis, cell survival, cell proliferation, and glycolysis. A central protein in this pathway is the von Hippel–Lindau protein (VHL), encoded by *VHL*. Under normal oxygen concentrations, VHL is a member of a multiprotein complex that promotes ubiquitin/proteasome-mediated degradation of HIF transcription factors. Hydroxylation of proline residues in HIF by the prolyl-hydroxylase PHD2 (EGLN1) is critical for VHL docking, a step crucial for ubiquitination.[43]

Inactivating germline mutations in *VHL* cause von Hippel–Lindau syndrome, an autosomal dominant disorder characterized by increased risk for several tumor types, including retinal, brain, and spinal cord hemangioblastomas, pancreatic neuroendocrine tumors, clear cell renal carcinomas, angiolymphatic sac tumors, and Pheo/PGL. Complete loss of VHL is usually a consequence of a somatic LOH event at 3p25.3. Consistent with increased angiogenesis, the tumors associated with VHL are rich in blood vessels. Interestingly, rare germline mutations in VHL that lead to mild defects in the protein function cause an autosomal recessive form of congenital erythrocytosis. This is presumably through global low-level activation of HIF-induced transcription, which leads to inappropriately high levels of erythropoietin, thereby inducing otherwise hypoxia-dependent erythrocytosis.[43] Recurrent somatic mutations in *VHL* have also been described in Pheo/PGL.[14]

In addition to *VHL*, mutations targeting another gene of the hypoxia pathway have been described in patients with syndromic forms of Pheo/PGL syndromes, including the polycythemia-paraganglioma-somatostatinoma syndrome. Genetically, this syndrome is characterized by a somatic mosaicism involving activating mutations of *EPAS1*, also known as *HIF2A*. These mutations also lead to constitutive activation of HIF-dependent transcriptional programs, leading to erythropoietin overproduction and tumor formation in target tissues.[44] Recurrent somatic mutations in *EPAS1* have also been described in sporadic Pheo/PGL.[14] Finally, mutations in genes encoding energy metabolism enzymes, including *SDH* family members (*SDHx*, encompassing *SDHA*, *SDHAF2*, *SDHB*, *SDHC*, and *SDHD*), *FH*, and *MDH2* lead to a metabolic switch that results in abnormal accumulation of metabolites (succinate or fumarate), which disrupt cell metabolism through the TCA cycle by inhibiting iron(II)- and α-ketoglutarate-dependent (α-KG) dioxygenases. These enzymes coordinate a broad spectrum of cellular programs. In particular, prolyl hydroxylases such as EGLN1, which are negative regulators of HIF stability, are inhibited by succinate and fumarate accumulation. TET enzymes, which coordinate DNA demethylation, are also inhibited by abnormal metabolite accumulation. TET inhibition leads to global epigenetic remodeling, including acquisition of the CIMP signature, thought to play a major role in tumorigenesis and in malignant transformation.[45,46] At the somatic level, the hotspot *IDH1* p.R132C mutation, which is known to dysregulate the TCA cycle through oncometabolite accumulation,[47] has also been described in a subset of sporadic Pheo/PGL.[14,48]

The other broad signaling pathway that is targeted by germline mutations in Pheo/PGL, activated kinase signaling,[41,42] is a growth-promoting pathway that promotes activation of translation and cell proliferation through MAPK. Transcriptional effectors of this signaling pathway include the MYC/MAX complex.[49] In Pheo/PGL, germline mutations associated with increased kinase activity include activating mutations of *RET*, inactivating mutations of *NF1*, and inactivating mutations in *TMEM127*, which cause multiple endocrine neoplasia type 2, neurofibromatosis type 1, and familial pheochromocytoma, respectively.[42] Mutations in *RET* occur at specific hotspots, including C634 and M918, and lead to the constitutive activation of its tyrosine kinase activity. Mutations in *NF1* are scattered throughout the gene and include large deletions. The protein NF1 is a negative regulator of the MAPK signaling pathway. Recurrent somatic mutations in *RET* and *NF1* have also been described in spontaneous Pheo/PGL, with *RET* mutations occurring at restricted hotspots.[14,50,51] Finally, germline mutations in *MAX*, which encodes MYC-associated factor X (MAX protein), are another cause of familial Pheo/PGL. Disruption of MAX promotes oncogenic effects of MYC. Recurrent somatic mutations in *MAX* have also been described in sporadic Pheo/PGL.[52] Constitutive activation of the MAPK pathway can also be triggered by mutations

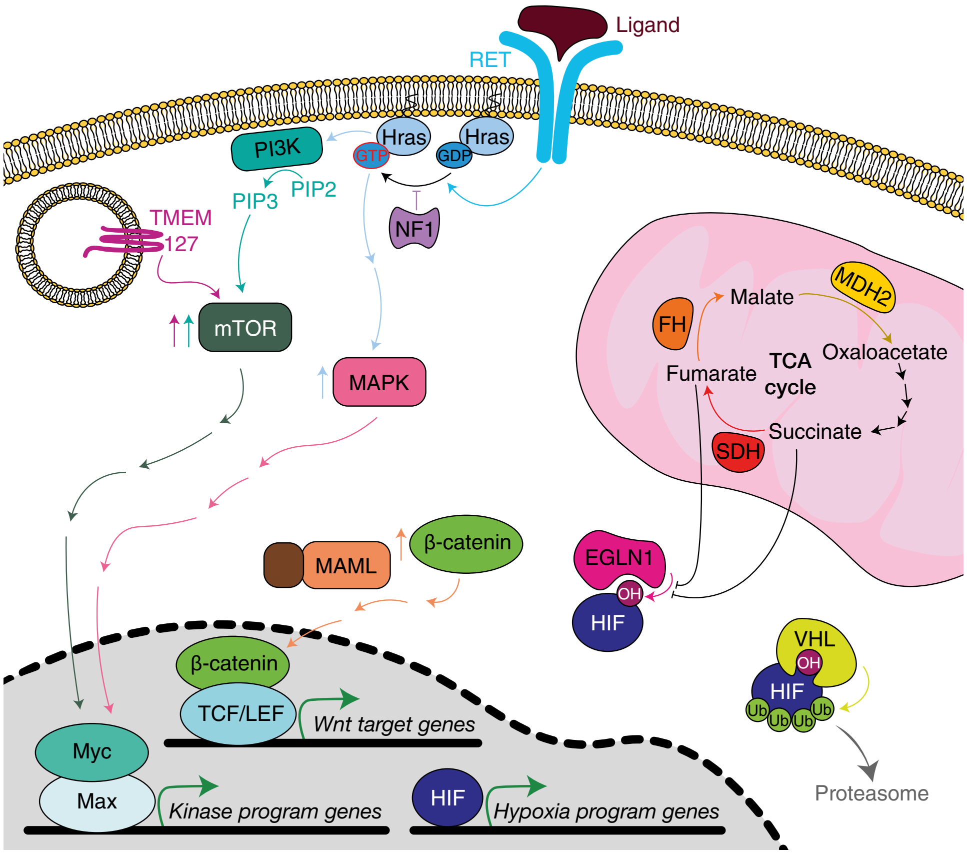

Fig. 95.5 Recurrent genetic alterations driving pheochromocytomas and paragangliomas (Pheo/PGL). Recent pangenomic studies of Pheo /PGL have revealed that these tumors are defined by activation of key cellular programs: cellular hypoxia signaling and activated kinase signaling. This is accomplished through alterations in genes encoding components of the TCA cycle (SDHx, FH, MDH2), effectors/putative modulators of receptor tyrosine kinase and mTOR/MAPK signaling (RET, NF1, HRAS, TMEM127, MAX), and critical regulators of cellular hypoxia (genes encoding hypoxia-inducible transcription factors, von Hippel–Lindau, and EGLN1). Sporadic Pheo also possess recurrent fusions targeting the *MAML3* locus, leading to expression of a chimeric fusion transcript and upregulation of Wnt/β-catenin–dependent transcription. How these different pathway components coordinate signaling cascades believed to drive expression of oncogenic programs is depicted in this figure. Notably, mutations in enzymes coordinating TCA cycle are frequently loss of function, driving the hypoxia program through aberrant accumulation of TCA metabolites (succinate and fumarate). Partially depicted, accumulation of succinate and fumarate inhibit several classes of enzymes including EGLN1 and TET enzymes that erase DNA methylation. Consequently, tumors bearing TCA cycle mutations also possess a DNA hypermethylation signature.

that only occur somatically in sporadic Pheo/PGL, such as hotspot mutations in *HRAS*.[14,53]

More recently, a study that performed multiplatform molecular profiling of a large number of Pheo/PGL identified novel recurrent somatic events, including mutations in *CSDE1* and gene fusions involving *MAML3*.[14] *CSDE1* encodes cold shock domain-containing E1, an RNA-binding protein involved in RNA stability, translation initiation, and neuronal development. Somatic mutations in *CSDE1* were present in 2% of the samples, usually affecting splicing sites, resulting in loss of function. Fusions involving *MAML3* were present in 5% of Pheo/PGL and involve the promoter regions of either *UBTF* or *TCF4* and the coding region of *MAML3*, resulting in in-frame chimeric transcripts. Because these resultant chimeric transcripts are overexpressed, *MAML3* fusions are presumably gain-of-function. Additional fusions were identified involving other genes, such as *KIAA1737-NGFR*, *RUNDC1-BRAF*, and *NF1-RAB11F1P4*. The first two result in overexpression of the kinase transcripts, and therefore are thought to be gain-of-function; the last results in disruption of *NF1* expression.

Other recurrent somatic mutations that reached statistical significance, according to this study, were the previously identified *HRAS*, *NF1*, *EPAS1*, and *RET* (present in 10%, 9%, 5%, and 3% of samples, respectively). In addition to these, somatic hotspot and cancer-relevant genes mutations in *BRAF*, *IDH1* (p.R132C), *FGFR1*, *VHL*, *ATRX*, *TP53*, *SETD2*, and *ARNT* were also detected. Importantly, unlike other tumor types that may have mutations in more than one driver gene, a striking mutual exclusivity was detected among somatic mutations and pathogenic germline variants detected in this study, indicating that tumors typically require only one mutation in this class of genes, except for *ATRX* mutations which usually cooccur with germline *SDHB* mutations, a previously described association.[54] Pathways relevant for Pheo/PGL biology are depicted in Fig. 95.5.

Integrated molecular classification of pheochromocytomas/paragangliomas: Multiomics profiling of Pheo/PGL have confirmed previous observations that prominent somatic and germline driver alterations converge on specific molecular subtypes.[41,42,51] Unsupervised consensus clustering analysis on the transcriptome data revealed that Pheo/PGL consists of four molecular subtypes, designated "kinase signaling," "pseudohypoxia," "Wnt-altered," and "cortical-admixture."[14] Consistent with previous studies, the "kinase-signaling" subtype was observed predominantly in epinephrine-producing adrenal pheochromocytoma of the "adrenergic" phenotype (see other chapters for a detailed discussion). This subtype was enriched for germline and somatic mutations targeting *NF1, RET, TMEM127,* and *HRAS,* as well as rarer fusion events involving *NF1, HRAS,* and *NGFR*. Furthermore, specific arm-level chromosomal deletions involving 1p, 3q, and 17q were also enriched in this subtype. Also consistent with previous observations, the "pseudohypoxia" subtype is enriched for germline mutations and somatic mutations in *SDHx, VHL, EPAS1,* and *EGLN1* (which were exclusive of this subtype) and non-epinephrine-producing Pheo/PGL. Other distinctive molecular features of the "pseudohypoxia" cluster include increased DNA methylation on CpG islands secondary to metabolite-dependent inhibition of DNA demethylases. Finally, whole-genome doubling events, characterized by extra copies of all chromosomes, were significantly enriched in the "pseudohypoxia" subtype, frequently in association with *VHL* and *EPAS1* mutations. The previously unappreciated "Wnt-altered" cluster exclusively consisted of sporadic adrenal pheochromocytomas, and was significantly enriched for *MAML3*-containing fusion transcripts and *CSDE1* mutations. This subtype features increased expression of targets of Wnt/β-catenin and Sonic Hedgehog pathways. Finally, the "cortical-admixture" subtype is characterized by increased expression of several adrenocortical genes, including *STAR, CYP11B2,* and *CYP21A2,* consistent with significant infiltration with cortical tissue. The presence of *MAX* mutations in this group, which is often associated with multifocal local disease, suggests that coalescing multiple tumor foci may "trap" cortical cells interspersed within the tumor.

SUMMARY AND FUTURE DIRECTIONS

Adrenal tumors are a heterogeneous group of diseases with diverse clinical phenotypes. This complexity is mirrored at the molecular level. A large number of genetic drivers targeting recurrent biological processes or molecular pathways have been described in sporadic and familial forms of adrenal tumors and are usually shared between the inherited and equivalent sporadic form. Within a similar tumor type, these genetic alterations cluster around molecular subtypes, which are biologically correlated groups of tumors based on unbiased multiomics classification. These molecular subtypes closely explain important aspects of the clinical variability, such as the endocrine manifestations, growth patterns, and disease prognosis. However, classifying a new tumor sample in a given molecular subtype outside the scope of a comprehensive multiomics study can be challenging. This task can be accomplished by the use of a biomarker, which is a single measurement of an analyte that can be used as a surrogate to identify a specific disease state. In adrenal tumors, these biomarkers can be hormones, mutations, or other molecular features, such as patterns of expression of specific genes, and targeted DNA methylation.[2,3,36,55-57] Examples of biomarkers for adrenal tumors include catecholamine/metanephrine levels to establish a diagnosis of Pheo/PGL, steroid profiling and *IGF2* expression to distinguish between ACA and ACC, steroid profiling and catecholamine/metanephrine levels to diagnose recurrence, expression levels of *BUB1B, PINK1,* and *G0S2,* and methylation levels of *G0S2* to diagnose highly recurrent/aggressive (C1A and ACC-TCGA COC3) subtypes of ACC. However, implementing biomarkers into clinical practice to aid into the decision-making process requires extensive validation, which is the goal of ongoing clinical studies.

Molecular subtypes, in particular, offer several meaningful insights that can be exploited therapeutically under the umbrella of personalized medicine as an alternative to the prevailing blanket therapy approaches. Molecular subtypes are particularly relevant for targeted therapies, such as kinase inhibitors, cell cycle inhibitors, epigenetic drugs, and immunotherapy. Early clinical trials using targeted therapies for adrenal tumors were disappointing.[58,59] However, these trials were performed at a time when the molecular subtypes were not fully characterized. In fact, small subgroups of patients exhibited measurable and long-term benefits from "failed" agents. Prospective identification of the potential responders could have changed the history of these trials, as molecular subtyping may more effectively narrow down likely responders according to the therapy's mechanism of action. In this setting, the use of molecular biomarkers is essential. However, the potential advantages should be extensively demonstrated and validated in preclinical studies and clinical trials in order to support this paradigmatic shift and justify the increase in cost and complexity of healthcare.

PATHOPHYSIOLOGY

Primary aldosteronism is a syndrome of inappropriate and relatively nonsuppressible renin-independent aldosterone production that persists despite expansion of effective arterial circulating volume and hypokalemia.

This autonomous production of aldosterone results in excessive activation of the mineralocorticoid receptor (MR) in the principal cell in the collecting duct, thereby inducing increased epithelial sodium channel mediated sodium reabsorption and consequent volume expansion. To maintain electroneutrality, the reabsorption of sodium in the distal nephron is paired with an obligate excretion of either potassium or hydrogen ions. This pathophysiology begets a vicious cycle: increased distal nephron sodium reabsorption contributes to increases in effective arterial circulating volume expansion, in turn increasing blood pressure and glomerular filtration, thereby resulting in suppression of renin and angiotensin II, which begets further increases in distal nephron sodium delivery, hence further increasing distal nephron sodium reabsorption.[1,2]

The cardinal features of primary aldosteronism (PA) include a suppression of baseline renin secretion, an inability to stimulate renin normally (despite provocation by upright posture, volume contraction or sodium depletion, or angiotensin-converting enzyme [ACE] inhibition), and inappropriate and nonsuppressible aldosterone production despite renin suppression.[3,4] Importantly, hypertension and hypokalemia are not obligate characteristics of PA; rather, they are dependent features that occur depending on the degree of intraarterial volume expansion and distal nephron sodium delivery.

The pathophysiology of PA extends beyond mechanisms in the kidney alone. The MR is expressed in the myocardium, vascular endothelium, smooth muscle, and other tissues. Animal experiments have elegantly demonstrated that, in contrast to the renin-dependent aldosteronism that is vital for the physiologic response to volume depletion, activation of the cardiovascular MR in the context of volume expansion and/or sodium-avid conditions results in myocardial fibrosis, necrosis, and clinical features of cardiovascular disease.[5-10] The molecular mechanism for this paradox remains unresolved: why is activation of the MR by aldosterone in volume/sodium-depleted states physiologic, whereas activation of the MR by aldosterone in volume/sodium-expanded states is pathophysiologic? However, observations from human studies have echoed these basic findings. Clinical trials in patients with heart failure with reduced ejection fraction (a state of increased left ventricular volume/pressure) have shown that MR antagonists dramatically reduce adverse clinical events and mortality.[11,12] Observational studies have suggested that patients with PA, compared with patients with essential hypertension, have a higher risk for coronary artery disease, congestive heart failure, left ventricular hypertrophy, atrial fibrillation, stroke, diabetes mellitus, metabolic syndrome, decreased bone density, and kidney disease.[2] Importantly, many of these observational studies demonstrated that the increased cardiometabolic risk associated with untreated PA, compared with essential hypertension, persists even when patients are matched for blood pressure and duration of hypertension.

PATHOGENESIS AND GENETICS

Primary aldosteronism results from autonomous production of aldosterone in the adrenal cortex. Under normal circumstances, aldosterone biosynthesis in the adrenal cortex is tightly regulated by the renin-angiotensin system and extracellular potassium concentrations to maintain blood volume, sodium, potassium and hydrogen homeostasis. The zona glomerulosa expresses the enzyme aldosterone synthase, encoded by *CYP11B2*, which catalyzes the three final enzymatic reactions leading to aldosterone biosynthesis.[13] Due to the expression of a large number of potassium channels[14] and the Na^+/K^+-ATPase, unstimulated zona glomerulosa cells show a strongly negative membrane potential, which parallels the potassium equilibrium potential. Angiotensin II and increased plasma potassium lead to cell membrane depolarization, followed by opening of voltage-gated calcium channels and increased intracellular calcium concentrations. Angiotensin II also acts by binding to its membrane G protein-coupled angiotensin II type 1 receptor that activates signaling via the inositol triphosphate pathway, increasing intracellular calcium levels from intracellular calcium stores. The increase in cytosolic calcium activates calcium signaling via calmodulin and calcium/calmodulin-dependent protein kinases,

TABLE 96.1 Genetic Forms of Primary Aldosteronism

Disease	Age of Onset	Specific Features	Gene	Transmission	Specific Treatment
Familial hyperaldosteronism type I	In most cases before age 20 yrs	Increased risk of cerebrovascular events before age 30 yrs; aldosterone suppressible by dexamethasone; increased urinary levels of hybrid steroids 18-oxocortisol and 18-hydroxycortisol	Chimeric *CYP11B1/B2*	AD	Glucocorticoids, MRA
Familial hyperaldosteronism type II	Variable, mostly in childhood	Usually mild, bilateral hyperaldosteronism	*CLCN2*	AD	MRA
Familial hyperaldosteronism type III	Before age 20 yrs Variable in mild forms	Massive bilateral adrenal hyperplasia in severe cases	*KCNJ5*	AD	MRA Bilateral adrenalectomy in severe cases
Familial hyperaldosteronism type IV	Variable, often in childhood	Developmental disorder in some cases	*CACNA1H*	AD	MRA
PASNA	Childhood	Seizures and neurological abnormalities	*CACNA1D*	*de novo* mutations	Calcium channel blockers, MRA
Familial hyperaldosteronism: genetic basis undefined*	Variable	None; diagnosis is based on two or more affected family members	To be determined*	Variable	Unknown

*The definition familial hyperaldosteronism reflects the clinical diagnosis. Genetic analysis allows identifying patients with chimeric *CYP11B1/B2, CLCN2, KCNJ5,* or *CACNA1H* mutations and reclassifying them as FH-I, -II, -II, or -IV, respectively. Other genes may be involved in cases without identified gene mutation.

PASNA, Primary Aldosteronism, Seizures and Neurologic Abnormalities; *AD*, autosomal dominant; *MRA*, mineralocorticoid receptor antagonists.

which is the major regulator of *CYP11B2* expression and aldosterone production.[15] In PA, regulatory mechanisms of aldosterone biosynthesis are bypassed by the chronic activation of intracellular calcium signaling resulting from different genetic defects.

Different genetic abnormalities have been identified in familial forms of PA and in aldosterone-producing adenoma (APA). While they occur as somatic mutations in APA, they are germline in familial cases and transmitted as an autosomal dominant trait. It is worth noting however, that somatic mutations also occur in the normal adrenal cortex in so-called aldosterone-producing cell clusters (APCCs) and in secondary aldosterone-producing nodules from adrenals with APA.

Familial Forms of Primary Aldosteronism

At least four different Mendelian forms of familial hyperaldosteronism (FH) have been reported (Table 96.1). They are defined as FH-I to FH-IV, depending on the underlying genetic defect. Familial forms occur in approximately 6% of patients with PA[16] and are transmitted as an autosomal dominant trait. Although these forms are rare, genetic screening should be offered to patients with early-onset PA before the age of 20 years and/or with a family history of PA, given the low cost and the benefits of early diagnosis in affected family members,[17] as deleterious cardiovascular effects due to aldosterone excess may occur well before patients become hypertensive.[18]

FH-I, also called glucocorticoid-remediable aldosteronism (OMIM #103900), is characterized by early and severe hypertension, usually before 20 years of age, biochemical abnormalities of PA, excessive production of the hybrid steroids 18-hydroxycortisol and 18-oxocortisol, and bilateral hyperplasia, in rare cases associated with adrenal nodules; remarkably, symptoms are relieved by treatment with dexamethasone.[19] FH-I is due to the presence of a chimeric gene resulting from an unequal crossing over between *CYP11B2* and the highly homologous *CYP11B1* gene coding 11β-hydroxylase, which is responsible for the last steps of cortisol biosynthesis in the adrenal zona fasciculata. The chimeric gene contains the regulatory regions of *CYP11B1* juxtaposed to *CYP11B2*-specific coding sequences. Therefore, aldosterone synthase is expressed ectopically throughout the adrenal cortex under the control of adrenocorticotropic hormone (ACTH) rather than angiotensin II.[20] Exogenous glucocorticoids are effective in reducing aldosterone synthase expression and aldosterone production. Low-dose glucocorticoids have been shown to be sufficient to normalize blood pressure and plasma potassium levels without affecting hormonal parameters, and may provide prolonged control of hypertension.[21] Mineralocorticoid antagonists or amiloride may be added in order to lower doses of glucocorticoids if required. In children, eplerenone is preferable, to avoid the side effects of glucocorticoids (retarded growth) or spironolactone (antiandrogen effects).[22] The prevalence of FH-I has been estimated to be approximately 0.5% to 1.0% of PA in the hypertensive adult population,[16,23] but its frequency appears to be higher in hypertensive children, where a prevalence of 3% of the chimeric *CYP11B1/CYP11B2* gene has been reported.[24] Although FH-I is a rare disease, it is associated with high morbidity and mortality before age 40 years from early-onset hemorrhagic stroke and ruptured intracranial aneurysms,[25] criteria that may orient diagnosis in affected patients. Abnormalities in cardiac structure and function may appear before the rise in blood pressure in carriers of the chimeric gene.[18] The genetic diagnosis is usually made by long-range polymerase chain reaction (PCR) or Southern blot, while urinary levels of 18-oxocortisol and 18-hydroxycortisol and the dexamethasone suppression test do not show as high sensitivity and specificity.[17]

FH-II (OMIM #605635), first described in 1991,[26] was originally defined as PA occurring in two or more family members (i.e., FH) that is not glucocorticoid-remediable and is not associated with the hybrid gene mutation. By that definition, it was reported to be the most frequent form of FH, accounting for approximately 1.2% to 6% of cases,[16,27] with a presentation undistinguishable from that of sporadic PA. Patients showed heterogeneous clinical presentations with varying aldosterone response on postural test and to angiotensin II and different subtypes of PA even within the same family.[28] Recently, germline mutations in *CLCN2*, coding for the chloride channel ClC-2, have been identified in a large Australian family with FH-II and in early-onset PA.[29,30] A recurrent germline *CLCN2* mutation was found in the first reported FH-II family, as well as in four additional unrelated patients,[29] while other *CLCN2* mutations were found in unrelated patients with early-onset PA.[29,30] This has led to the term "FH-II" being restricted to PA caused by germline *CLCN2* mutations. *CLCN2* encodes a voltage-gated chloride channel composed of 18 transmembrane helices and an intracellular N-terminus and C-terminus. Mutations are mostly located in particular regions of the protein and induce a loss of the voltage gating of the channel. Thus, the channel is constitutively open at the zona glomerulosa resting potential, leading to sustained chloride efflux, followed by cell membrane depolarization, activation of calcium signaling, and increased expression of aldosterone synthase and autonomous aldosterone production.[29,30] In addition to *CLCN2* mutations, some patients previously diagnosed with FH-II harbor mutations in genes identified in other familial forms and are therefore reclassified after genetic diagnosis. In particular, germline *KCNJ5* mutations are found in patients with a moderate phenotype resembling FH-II,[31,32] as well as mutations in *CACNA1H*.[33] Somatic mutations of *KCNJ5* were also reported in APA from patients diagnosed with FH-II according to the clinical definition.[32] Hence, the phenotype of FH includes different subtypes of FH, which, in the absence of discriminating clinical features, require genetic testing for classification. In addition, there may be some cases in which FH results from familial aggregation of sporadic PA, given the high frequency of the condition in patients with hypertension.

FH-III (OMIM #613677) is a rare form of FH characterized in most patients by severe hypertension early in childhood that is refractory to treatment and associated with severe hypokalemia and massive bilateral adrenal hyperplasia.[34] The hybrid steroids 18-oxocortisol and 18-hydroxycortisol in urine are increased, but aldosterone production is not suppressed by dexamethasone.[34] FH-III is due to recurrent mutations of the *KCNJ5* gene coding for the G protein-activated inward rectifier potassium channel GIRK4.[35] Some heterogeneity in the clinical presentation, particularly in the severity of the disease, has been described, which appears to be associated with the type of mutation.[31,32] Some patients present a particularly mild form of PA, diagnosed in young adulthood, with or without hypokalemia with no evident signs of hyperplasia at imaging. This form responds well to pharmacological treatment with MR antagonists and had often been previously diagnosed as FH-II.[31,32] Almost all *KCNJ5* mutations are located within or near the selectivity filter of the GIRK4 potassium channel. They induce a change in ion selectivity, with loss of potassium selectivity and increased sodium conductance. This leads to increased sodium influx into the cell, followed by opening of voltage-gated Ca^{2+} channels, activation of Ca^{2+} signaling, and stimulation of aldosterone biosynthesis.[35,36] Pathological examination of the adrenal gland in two affected individuals after adrenalectomy has shown adrenal enlargement with loss of zonation and expression of aldosterone synthase throughout the adrenal cortex.[37] Coexpression of 11β-hydroxylase or 17α-hydroxylase with aldosterone synthase in some adrenal areas explains the increased levels of hybrid steroids in these patients. In one patient carrying a *KCNJ5* mutation, cosecretion of aldosterone and cortisol has been reported.[38]

A fourth form of FH, FH-IV (OMIM #617027), has been discovered by whole-exome sequencing of patients with early-onset PA before the age of 10 years.[33,39] A recurrent mutation in the *CACNA1H* gene was identified in five patients, with autosomal dominant transmission in four families and a *de novo* mutation in one case.[39] In parallel, different *CACNA1H* mutations were reported in patients with early-onset PA or with mild PA diagnosed as FH-II.[33] In some cases, *CACNA1H* mutations are associated with developmental disorders or attention deficit.[33,39] In most cases, no adrenal abnormalities are observed on imaging, but in one case, the pathological examination of the resected adrenal has shown micronodular adrenal hyperplasia.[39] *CACNA1H* encodes the pore-forming α1 subunit of the T-type voltage-dependent calcium channel Cav3.2. The channel is composed of four repeat domains (I–IV), each consisting of six transmembrane segments (S1–S6), and mediates voltage-dependent calcium influx into the cell upon membrane depolarization. Cav3.2 mutations affect highly conserved amino acids of the protein, modifying important channel properties. In particular, they shift the voltage dependence of the channels towards more negative membrane potentials, inducing channel opening at less depolarized membrane potentials, and/or delay the voltage-dependent inactivation of the channel. The functional consequence is sustained calcium influx into the cell, activating calcium signaling and aldosterone biosynthesis.[33,39]

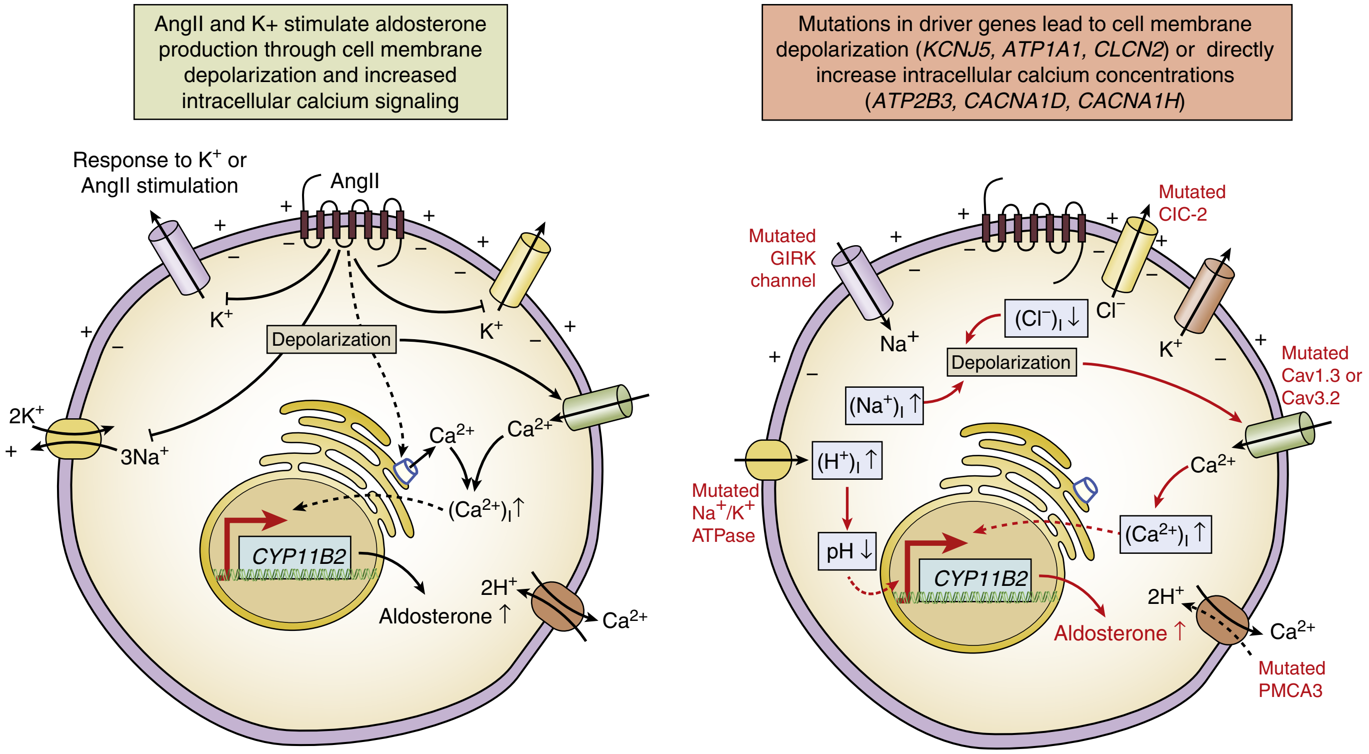
A particular form of PA that is not inherited, but rather due to germline mutations affecting another calcium channel, is PASNA (Primary Aldosteronism, Seizures, and Neurologic Abnormalities; OMIM #615474). In this condition, mutations affect the *CACNA1D* gene, coding for the voltage-dependent L-type calcium channel subunit alpha-1D.[40] Those patients show early onset PA in the context of a complex neurological disorder, including cerebral palsy and epileptic seizures. Patients have severe hypertension and hypokalemia, without adrenal hyperplasia on imaging, and carry *de novo* germline mutations of the *CACNA1D* gene. The disease has been described in only four patients so far, in one case associated with congenital hyperinsulinism, and its prevalence is currently unknown.[40-42] The pathogenic mechanism whereby *CACNA1D* mutations lead to PA is similar to FH-IV: the mutations affect the channel properties, leading to opening of the channel at less depolarized membrane potentials and activation of calcium signaling and aldosterone biosynthesis.

Somatic Mutations in Unilateral Primary Aldosteronism

The majority of cases of PA occur sporadically and are due to a unilateral APA or bilateral adrenal hyperaplasia. From a clinical point of view, the distinction is made based on unilateral versus bilateral aldosterone secretion defined by adrenal venous sampling (AVS). From a pathological point of view, it has become apparent that unilateral forms encompass a large variety of morphological alterations, ranging from an isolated APA to multinodular adrenals. Recurrent somatic mutations are found in a majority of APAs, as well as aldosterone-producing structures in adrenal glands from patients with PA.[43-46] They affect genes involved in familial forms of the disease (*KCNJ5*, *CACNA1H*, *CLCN2*), as well as genes coding for ATPases (*ATP1A1,* coding for the α1 subunit of the Na^+,K^+-ATPase, and *ATP2B3,* coding for the plasma membrane calcium-transporting ATPase 3 [PMCA3]) and *CACNA1D*, coding for the α1 subunit of the L-type Ca^{2+} channel Cav1.3. In certain cases, somatic mutations have been identified in genes mainly involved in adrenal disorders associated with cortisol excess. Indeed, 2% to 5% of APAs carry somatic mutations in *CTNNB1*, coding for β-catenin.[47-49] Somatic mutations affecting *PRKACA* (coding for catalytic alpha subunit of the cAMP-dependent protein kinase) have been described in rare cases as well, and may be associated with cortisol excess.[50]

Somatic mutations affect specific conserved amino acids of the proteins and lead to major functional modifications. They can be classified in two major categories: those that lead to cell membrane depolarization by altering intracellular ion homeostasis (*KCNJ5*, *ATP1A1*, *CLCN2*), and those that directly increase intracellular calcium levels by affecting calcium channels and pumps (*ATP2B3*, *CACNA1D*, *CACNA1H*) (Fig. 96.1).

As described for FH-III, the most prevalent mutations in *KCNJ5* lie within or near the selectivity filter of GIRK4 and modify the ion selectivity of the channel, rendering it permeable to sodium.[35,36] Mutations in *ATP1A1* decrease the activity of the sodium potassium ATPase and reduce the affinity for K^+,[51] while mutations in



AngII and K+ stimulate aldosterone production through cell membrane depolarization and increased intracellular calcium signaling

Fig. 96.1 Different mechanisms lead to APA formation. Following increase of extracellular potassium or AngII binding to its AT1R receptor, inhibition of potassium channels leads to cell membrane depolarization and opening of voltage gated calcium channels. Increased intracellular calcium concentrations lead to activation of calcium signaling, which induces aldosterone biosynthesis. Binding of AngII to AT1R also inhibits Na+/K+-ATPase, inducing cell membrane depolarization, while AT1R signaling through Gαq promotes the release of calcium from intracellular calcium stores (left panel). Mutations in *KCNJ5*, coding for the potassium channel GIRK4, change the channel's ion selectivity, promoting sodium entry into the cell instead of potassium efflux, leading to cell membrane depolarization and opening of voltage gated calcium channels. Mutations in *ATP1A1*, coding for the α1 subunit of the Na+/K+-ATPase, lead to increased aldosterone production by increasing intracellular Na+ and H+ concentrations, resulting in cell membrane depolarization and decrease of intracellular pH. Mutations in *CLCN2*, coding for the chloride channel ClC-2, lead to increased chloride efflux from the cell, similarly leading to cell membrane depolarization. Mutations in *CACNA1D*, encoding the Cav1.3 calcium channel, *CACNA1H*, encoding the Cav3.2 calcium channel, and *ATP2B3*, coding for the Ca2+ pump PMCA3 directly affect intracellular calcium concentrations and thus aldosterone biosynthesis (right panel). Ca2+, calcium; K+, potassium; Na+, sodium; Cl-, chloride. (Modified from Zennaro, et al. *Endocr Rev* **38**, 516-537 (2017).)

CLCN2 act by increasing chloride efflux as in FH-II.[52] On the other hand, *ATP2B3* mutations decrease pump activity of the PMCA3, impairing calcium export. In addition, *ATP2B3* mutations may also induce a sodium leak, inducing cell membrane depolarization as well as a calcium leak through mutated pumps.[53] *CACNA1D* and *CACNA1H* mutations have similar functional consequences. They shift the voltage dependency of the mutated calcium channels towards more negative potentials, therefore leading to the channels opening at less depolarized potentials upon stimulation, or delay their voltage-dependent inactivation.[33,40,54] *In fine*, both these mechanisms increase intracellular calcium concentrations and lead to activation of calcium signaling, activating molecular cascades triggering increased expression of aldosterone synthase and autonomous aldosterone production.

The most frequent somatic mutations found in APA are *KCNJ5* mutations. They account for around 40% of adenomas,[55,56] with higher frequencies in patients from East Asia.[56] These figures were not changed by the introduction of CYP11B2 immunohistochemistry-guided next-generation sequencing.[43-46] In contrast, the prevalence of somatic mutations in other genes increased significantly following next-generation sequencing, which allows extended coverage of genes. *CACNA1D* mutations are now identified in 14% to 42% of APAs, *ATP1A1* mutations in 5% to 17% of APAs, and *ATP2B3* mutations in 4% to 10% of patients, depending on the population.[43-46] *CACNA1H* and *CLCN2* mutations are found in rare cases.[52,57]

Somatic Mutations in Bilateral Adrenal Hyperplasia

Idiopathic hyperaldosteronism, or bilateral adrenal hyperplasia, is diagnosed on the basis of bilateral secretion of aldosterone at AVS, and treatment with MR antagonists is the recommended therapeutic approach. A recent study had the opportunity to investigate 15 adrenals from patients with idiopathic hyperaldosteronism who had undergone adrenalectomy for exceptional reasons, including difficult-to-control hypertension or hypokalemia and unwillingness for long-term medical treatment. An increased number of so-called APCCs of the adrenal cortex was identified, which carried somatic mutations in *CACNA1D*, as well as a *KCNJ5* mutation in a micronodule.[58] APCCs are clusters of cells located in the zona glomerulosa, express CYP11B2, and are composed of an outer part of compact cells expressing disabled-2, a marker of the zona glomerulosa, and an inner part of larger cells not expressing disabled-2, suggesting that they may be intermediate structures between the zona glomerulosa and the zona fasciculata.[59,60,70,72] In normal adrenals, the number of APCCs increases with age and progressively replaces the continuous zona glomerulosa observed in younger individuals; this is associated with an age-related dysregulation of aldosterone production.[61] The peculiar feature of APCCs is that they carry somatic mutations even in normal adrenal glands, and therefore have been suggested to represent a possible precursor of APA.[60] Whether or not an accumulation of APCCs carrying somatic mutations underlies the development of idiopathic hyperaldosteronism in general, or rather is a contributor to autonomous aldosterone production in hyperplastic glands, requires further studies. Indeed, APCCs are also present in adrenals with APA and may carry different somatic mutations in the same adrenal gland.[45]

New Diagnostic and Therapeutic Opportunities Associated with Genetic Knowledge

One important question is whether genetic knowledge may improve diagnosis and treatment of patients with PA. There is no doubt that genetic diagnosis in familial forms allows for earlier detection of affected family members and better prevention of cardiovascular complications that may occur before hypertension onset.[18] On the other hand, identification of somatic mutations in resected adrenal glands has not provided benefit to patients so far. Identification of surrogate biomarkers of the presence of somatic mutations may eventually allow simplification of the diagnostic procedure by identifying patients likely to carry a unilateral APA to be selected for AVS. Some attempts have indicated that steroid profiling in peripheral vein samples may provide good information on the presence of somatic mutations. Indeed, levels of the hybrid steroids 18-oxocortisol and 18-hydroxycortisol are significantly higher in patients with *KCNJ5* mutations compared with other mutational groups,[62,63,45] and steroid fingerprints have been applied for distinguishing different genetic groups.[62] Similarly, the pharmacological properties of mutated GIRK4 channels are currently used to test the hypothesis that macrolides may be used for diagnostic purposes.[64] These approaches may be used together with peculiar imaging characteristics of APA carrying *KCNJ5* mutations on computed tomography, which are characterized by larger tumor size and lower precontrast Hounsfield units,[48] as well as the high prevalence in young patients and in women,[55,56] to elaborate a decision tree guiding diagnostic assessment. It is therefore the purpose of ongoing genetic studies not only to understand the development, but also to allow for personalized approaches to diagnosis and management of patients with PA.

KEY POINTS

- Mutations in different genes coding for ion channels (*KCNJ5*, *CACNA1D*, *CACNA1H*, *CLCN2*) and ATPases (*ATP1A1*, *ATP2B3*) are found in familial hyperaldosteronism and in aldosterone-producing adenoma. They lead to cell membrane depolarization, followed by opening of voltage-gated calcium channels, or directly increase intracellular calcium concentrations, with activation of calcium signaling leading to increased aldosterone biosynthesis.

PREVALENCE

Iterative population-based and convenience sample-based studies have shown that the prevalence of PA is high and largely underestimated. The challenge in establishing accurate prevalence estimates has been the lack of a histopathologic or other gold-standard reference diagnostic. Rather, the diagnosis of PA is made using a variety of arbitrary screening and confirmatory diagnostic thresholds; variations in these diagnostic thresholds can easily modulate prevalence estimates.

Population-based studies that used the aldosterone-to-renin ratio (ARR) have suggested that 7% to 12% of the hypertensive population may have PA,[65,66] and that higher aldosterone levels in the context of suppressed renin activity were associated with higher risk for incident coronary artery calcification and all-cause mortality.[67] Many international studies have used a two-tiered approach to estimate prevalence, wherein the ARR is first used to identify a "positive" screen, which is then confirmed using a variety of physiologic or dynamic confirmatory tests designed to evaluate aldosterone suppressibility.[68-76] Collectively, these studies have shown that overt PA can be detected in 2% to 19% of hypertensive individuals, with the prevalence paralleling the severity of hypertension. In contrast, some studies have estimated prevalence by conducting dynamic aldosterone suppression tests in hypertensive individuals without antecedent ARR screening and have reported much higher prevalence estimates, presumably because many ARRs are considered to be falsely "negative" owing to the variability of aldosterone production and the arbitrary nature of screening thresholds.[77] For example, 28% to 30% of participants with hypertension were confirmed to have PA when undergoing direct dexamethasone-fludrocortisone suppression testing,[78] 29% of patients with resistant hypertension were confirmed to have PA when undergoing direct saline suppression testing,[79] and 24% of patients with resistant hypertension were confirmed to have PA when undergoing direct oral sodium suppression testing.[80] Beyond these crude prevalence estimates born out of reliance on arbitrary thresholds for diagnosis, studies have shown a continuum of renin-independent aldosterone production in hypertension that is associated with the severity of hypertension and kaliuresis,[80,81]; thus, suggesting that the prevalence of PA captured using binary diagnostics likely underestimates the true burden of pathogenic aldosteronism.

The clinical relevance of this high prevalence of PA and the continuum of renin-independent aldosterone is the association of this biochemical phenotype with incident cardiometabolic disease that can be mitigated by MR antagonists[82-84] or, in patients with unilateral PA, unilateral adrenalectomy. Intervention studies have consistently shown that, the greater the magnitude of the renin-independent aldosterone production, the greater the efficacy of MR antagonists in lowering blood pressure.

Finally, although clinical indications for PA screening generally focus on individuals with hypertension, accruing evidence indicates that a PA phenotype can be detected even among those with normal blood pressure (sometimes referred to as subclinical or nonclassical PA[85]). Multiple studies that have used dynamic confirmatory testing have observed that approximately 9% to 14% of normotensive participants have nonsuppressible aldosterone production that meets conventional definitions for diagnosing PA.[80,86-90] In parallel with these observations, population-based studies have shown that this biochemical phenotype of renin-independent aldosterone production in normotensive people is associated with an increased risk for developing incident hypertension,[65,91-93] thereby suggesting a pathologic continuum of PA that may have its origins in normotension and may contribute to the pathology of hypertension.

CLINICAL DIAGNOSIS

Symptoms and Signs of Primary Aldosteronism

The great majority of patients with PA are hypertensive. Within some families with inheritable forms, blood pressure levels in members testing positive for the causative mutation and demonstrating biochemical evidence of PA have varied from normal to severely elevated.[94,95] Occasional normotensive patients with apparently nonfamilial PA, usually heralded by hypokalemia rather than hypertension, have also been described. Hypokalemia is now known to present in a minority (approximately 20%–25%) of patients, and hence its absence does not exclude PA.[96,97] When it is present, associated symptoms may include muscle weakness, cramping, tetany, paresthesias, palpitations, polyuria, and nocturia. Nocturia often occurs even when plasma potassium is normal and may reflect the rise in atrial natriuretic peptide levels that has been associated with PA or low intracellular renal levels of potassium resulting from increased release in an attempt to maintain normokalemia. Other common symptoms in patients with PA include lethargy, impaired mental concentration, and mood disturbances.[98-101]

Hypertension and symptoms may be masked during pregnancy[102,103] due to the high circulating levels of placental progesterone (which is an MR antagonist). In other women, development of PA due to APA during pregnancy has been linked to the presence of somatic activating mutations in *CTNNB1* that encodes β-catenin in the Wnt cell differentiation pathway (possibly explaining tumor development) and increased expression of *LHCGR* (encoding lutotropin-choriongonadotropic hormone receptor) and *GNRHR* (encoding gonadotropin-releasing hormone receptor), suggesting that high levels of human chorionic hormone during pregnancy may result in stimulation of aldosterone production by these APAs via aberrant receptor activation.[47]

Once thought not to occur in PA, malignant hypertension has been reported by several investigators.[104,105] The intrarenal ischemia that occurs in this may lead to unsuppression of renin, which could result in the diagnosis of PA being missed.

Assays Used in the Diagnostic Workup of Primary Aldosteronism

Highly reproducible assays are essential for all stages of the diagnostic workup of PA, including screening, confirmatory suppression testing, and AVS.

Aldosterone Assays. Accurate and reproducible measurement of plasma or serum aldosterone is a challenge for clinical laboratories, because it circulates at relatively low (picomolar) concentrations. Although radioimmunassays were until recently the most widely used method of measuring aldosterone, these have now been replaced in many laboratories by faster and less labor-intensive automated platforms using immunometric assay technology. Concerns have been raised regarding the accuracy of immunoassays in general and the need for high-affinity, highly specific antibodies and meticulous laboratory technique. Lack of specificity probably explains why newer, highly accurate and reproducible methods of measuring aldosterone within the clinically relevant range using high-performance liquid chromatography and tandem mass spectrometry (LC-MS/MS) generate aldosterone levels that are substantially lower than those measured by immunoassays within the same plasma samples,[106,107] necessitating adjustment of diagnostic thresholds such as the ARR and confirmatory suppression testing.[108,109] These methods, previously laborious and time-consuming, now employ semiautomated technology, which allows high sample throughput and faster generation of assay results, making them suitable for the clinical setting. While running costs are relatively low, the initial cost outlay associated with purchasing the equipment represents a barrier to wide application of LC-MS/MS, a situation that may change with time.

Renin Assays. The most commonly utilized renin assay methods are the measurement of plasma renin activity (PRA) or of direct (or active) renin concentration (DRC). Each has its advantages and disadvantages. PRA measures (usually by radioimmunoassay, but in some laboratories by LC-MS/MS) the amount of angiotensin I generated by the action of renin on its substrate, angiotensinogen, in a defined volume of plasma per unit of time, and hence is a measure of renin enzyme activity. For samples with levels less than 1 ng/mL/min, reproducibility of the assay can be maintained by extending the incubation time from the recommended 90 minutes to 18 hours.[110]

The principal advantage of DRC, which measures the plasma concentration of the active (cleaved) form of renin, is that it can be undertaken by automated immunometric assay,[111] which is much faster and less labor-intensive than PRA. Some laboratories offer combined aldosterone and renin measurement on the same sample using automated immunometric technology. However, concern has been raised over the lack of reliability and reproducibility of these assays at the lower end of the human reference range, which is especially pertinent for the diagnostic workup of PA, where renin levels are suppressed. In this situation, small changes in renin can result in large changes of the ARR,[112] and it could therefore be argued that it is more important to measure renin accurately than aldosterone when screening for PA.

A further concern for DRC measurement is that it may not reflect the true activity of the renin-angiotensin system as well as PRA. Renin does not affect blood pressure or aldosterone synthesis directly, but only through angiotensin II, concentrations of which may be better reflected by PRA. For example, with administration of exogenous estrogen (in oral contraceptive or hormone replacement preparations), the concentration of angiotensinogen (substrate) increases, and DRC falls to maintain angiotensin II concentrations in the normal range, whereas PRA remains relatively unaffected.[113,114] On the other hand, advocates for automated immunometric renin assays have reported that they appear to have better interlaboratory agreement.[115]

A potential alternative to the measurement of renin in the diagnostic workup of PA is recently reported mass spectrometric methods of assaying angiotensin I (generated from angiotensinogen as per the PRA approach) or, more promising still, angiotensin II (measured during a period of equilibrium of formation versus metabolism). Unlike renin, angiotensin II directly regulates aldosterone synthesis via AT1 receptors on adrenal zona glomerulosa cells, and its measurement is therefore arguably more physiologically relevant in clinically assessing patients for the presence of angiotensin II-independent aldosterone overproduction.[116]

Diagnostic Workup for Primary Aldosteronism

This is divided into three main phases: screening, confirmatory testing, and determining the subtype of PA. All require expertise for optimal performance and interpretation of results and are the subject of considerable ongoing research efforts towards refinement.

Screening. Screening of at-risk populations for PA is primarily geared towards identifying those patients who do not have this condition, and therefore are not required to undergo confirmatory testing and subtype differentiation (both of which involve procedures that are relatively invasive and expensive). It is therefore important that the screening test is highly sensitive, while retaining a reasonable degree of specificity.

Most patients with hypertension, and especially those with moderate to severe forms, should be regarded as candidates for screening. In addition, screening is recommended for patients with hypertension and spontaneous or diuretic induced hypokalemia, adrenal incidentaloma, sleep apnea, or a family history of early-onset hypertension or cerebrovascular accident at a young age (<40 years), and all first-degree relatives of patients with PA.[22] Some investigators suggest screening of all hypertensives, given the high prevalence of this condition among the hypertensive population and the reported short- and long-term benefits from specific surgical or medical treatment.[117] Screening before commencement of antihypertensive medications avoids potentially confounding effects of these agents on renin and aldosterone levels and permits earlier institution of specific treatment, which has been shown to be a major determinant of benefit achieved (including the chance of cure of hypertension following unilateral adrenalectomy for unilateral forms of PA).[118] Contrary to previous thinking, it is no longer considered appropriate to restrict screening to hypertensive patients with hypokalemia, as this would lead to as many as 80% of patients with PA being missed.[96]

Currently the most popular method of screening for PA involves the measurement of the plasma ARR. This is based on the lack of sensitivity of the demonstration of hypokalemia or of frankly elevated plasma aldosterone levels,[97,119] and also the lack of specificity of suppressed renin levels (which are also observed in patients receiving β-adrenergic or nonsteroidal antiinflammatory agents, ingesting a high dietary salt intake, of advanced age, or with chronic kidney disease or other varieties of low renin hypertension such as Liddle syndrome, hypertensive forms of congenital adrenal hyperplasia, familial hypertension and hyperkalemia, the syndrome of apparent mineralocorticoid excess, ectopic ACTH syndrome, deoxycortisone-secreting tumor, or glucocorticoid resistance states). Normal aldosterone levels could be viewed as "inappropriately normal" in the face of renin suppression, because individuals without PA should exhibit low plasma aldosterone levels in such situations. Raised aldosterone levels also lack specificity, as they may be secondary to activation of the renin-angiotensin system (secondary hyperaldosteronism) due, for example, to treatment with diuretics or renovascular hypertension. The ARR is much more sensitive for detection of PA than plasma potassium or aldosterone measured in isolation, and more specific than isolated renin, in that aldosterone is also suppressed in most other salt-dependent low-renin forms of hypertension, and hence the ARR is not elevated.

False-positive and false-negative ARRs can result from a variety of physiological and pharmacological factors (Tables 96.2 and 96.3), an appreciation of which aids substantially in the optimal performance of ARR testing and interpretation of results. The most common of these are medications, with β-adrenoceptor blockers, clonidine, α-methyldopa, nonsteroidal antiinflammatory drugs and estrogen-containing oral contraceptive agents or hormone replacement therapy prone to cause false positives, and diuretics (including potassium-sparing), ACE inhibitors, angiotensin receptor blockers (ARBs), dihydropyridine-type calcium channel blockers, and selective serotonin receptor inhibitors having the potential to cause false negatives.[120,121] Where possible, antihypertensives known to affect the ARR should be withdrawn (for at least 4 weeks for diuretics and at least 2 weeks for other agents) prior to screening. Antihypertensive medications that appear to have minimal, if any, effects on the ARR and can be used to control hypertension (where necessary) during screening and subsequent steps in the diagnostic workup of PA include verapamil SR, hydralazine (best used in combination with verapamil SR to avoid reflex tachycardia), prazosin, doxazosin, and moxonidine.[121] ARR testing while patients are still on interfering medications can still be informative. For example, a raised ARR with suppressed renin in a patient receiving an ACE inhibitor, ARB, or diuretic would be highly suggestive of PA, whereas a normal ARR in a patient on a β-blocker would make PA highly unlikely.

Other circumstances in which false positives can be encountered include the luteal phase of the menstrual cycle in premenopausal women, advancing age, chronic kidney disease, a high dietary salt intake, and the syndrome of familial hyperkalemic hypertension (Gordon syndrome). False negatives may occur during pregnancy, dietary salt restriction, vomiting or diarrhea, or uncorrected hypokalemia, and in patients with malignant hypertension or concomitant renovascular hypertension.[121]

The ARR has greater sensitivity if measured in the morning in an upright (e.g., seated) posture. Controlling for the above factors or at least taking them into account enhances the usefulness of ARR testing in selecting patients for further diagnostic workup. The ARR also shows good within-patient reproducibility under such conditions.[122]

One limitation of the ARR is that, in the presence of extremely low renin levels (for example, a DRC of 1.5 mU/L or PRA 0.1 ng/mL/h or less), the ARR may be elevated and thereby raise the possibility of PA even when plasma aldosterone is also very low (for example, 110 pmol/L or 4 ng/dL) and clearly not consistent with PA. While some investigators have suggested the inclusion of a minimum plasma aldosterone concentration (for example, 415 pmol/L or 15 ng/dL) to accompany an elevated ARR within the screening criteria in an attempt to overcome this problem,[123] others have found this to exclude many patients who have subsequently been confirmed as having PA.[119]

The ratio should be regarded as a screening test only, and should be measured more than once before deciding whether or not to go on to confirmatory testing for PA.

Confirmatory Testing. Because the ARR can be falsely positive even under ideal testing conditions, confirmatory testing is required to definitively confirm or exclude the diagnosis of PA. This important step allows selection of patients with confirmed PA for further testing, including AVS, to determine the subtype. Conversely, exclusion of PA spares patients from having to undergo this invasive and relatively expensive and difficult procedure.

Confirmatory testing usually involves measuring aldosterone during maneuvers designed to bring about complete suppression of circulating renin, and therefore of aldosterone's normal chronic regulator angiotensin II. Failure of aldosterone to suppress confirms aldosterone production that is relatively autonomous of angiotensin II, the *sine qua non* of PA.

Of the various approaches described, the most common confirmatory tests in use are the oral sodium loading test, the saline infusion testing, and the captopril challenge test. Fludrocortisone suppression testing (FST) is regarded by some investigators to be the most reliable, but is relatively labor-intensive and requires a 5-day admission to hospital, during which the plasma aldosterone response during 4 days of oral administration of fludrocortisone (0.1 mg 6 hourly) and oral salt loading (by high sodium diet and administration of slow-release sodium chloride tablets, 1800 mg three times daily with meals) is assessed.[124] The FST is considered diagnostic of PA if upright (seated) 1000-h plasma aldosterone fails to suppress to less than 6 ng/100 mL (165 pmol/L) at the conclusion of the test, provided that renin has been sufficiently suppressed, plasma potassium has been maintained in the normal range by adequate slow-release KCl supplementation (given 6 hourly), and there has been no rise in cortisol during the morning of the final day to suggest a rise in ACTH that might have prevented suppression of aldosterone.

For the oral salt loading test, patients are instructed to consume sufficient dietary salt to achieve a urine sodium excretion of over 200 mmol/day and are given adequate KCl supplementation to maintain normokalemia. A 24-h urinary aldosterone concentration of over 12 μg/day (33 nmol/day) on the third day is regarded as diagnostic.[123]

The saline infusion test (or saline suppression test [SST]) involves intravenous administration of 0.9% saline (usually 2 L over 4 hours) with measurement of plasma aldosterone at the end of the infusion, traditionally while patients are maintained in the recumbent position (unlike FST, in which the diagnostic plasma aldosterone level is collected while the patient is seated following at least 2 h of upright posture). Concentrations regarded as diagnostic for PA have varied from greater than 5 to greater than 10 ng/100 mL (>140 to >280 pmol/L).[125,126] A major advantage of this approach over FST is that it can be performed as an outpatient procedure. However, concerns have been raised over its lack of sensitivity, especially in patients in whom plasma aldosterone demonstrates responsiveness to the assumption of upright posture, as their recumbent aldosterone levels are lower than those in posture-unresponsive patients.[127] A recently reported approach has been to perform SST in the seated position, resulting in substantially improved sensitivity for detecting PA while retaining high specificity.[128] By this method, diagnostic cutoffs for normal

TABLE 96.2 Factors Causing False-Positive Aldosterone-to-Renin Ratios

	Effect on Aldosterone	Effect on Renin	Mechanism
β-blockers	↓	↓↓	Blockade of JG cell beta-adrenergic receptors
Clonidine α-methyldopa	↓	↓↓	Suppression of CNS sympathetic output
NSAIDs	↔	↓↓	Tendency to Na^+ retention and suppression of renal prostaglandins (which normally enhance release of renin) leads to renin suppression Tendency to K^+ retention prevents fall in aldosterone
Estrogen- and progestogen-containing agents*	↑	↔	Progestogenic component induces natriuresis, which stimulates renin and aldosterone Estrogenic component stimulates renin substrate (angiotensinogen) and thus angiotensin production, resulting in greater negative feedback on renin (and hence DRC), thereby opposing the stimulatory effects of the progestogenic component
Premenopausal women in luteal menstrual phase*	↑	↔	Progesterone induces natriuresis which stimulates renin and aldosterone Estrogen stimulates renin substrate and thus angiotensin production, resulting in greater negative feedback on renin
Advancing age	↔	↓↓	Reducing nephron (and JG cell) number and tendency to Na^+ retention leads to renin suppression Tendency to K^+ retention prevents fall in aldosterone
Chronic kidney disease	↔	↓↓	Reducing nephron number and tendency to Na^+ retention leads to renin suppression Tendency to K^+ retention prevents fall in aldosterone
High dietary Na^+	↓	↓↓	Suppression of renin (to a greater degree than aldosterone)
Familial hyperkalemic hypertension	↔	↓↓	Mutations in *WNK1*, *WNK4*, *CUL3* or *KLH3L* cause upregulation of NCC. Resulting Na^+ retention leads to renin suppression and K^+ retention prevents fall in aldosterone

*False positives only occur if renin is measured as direct renin concentration (and not plasma renin activity).

JG, Juxtaglomerular; *CNS*, central nervous system; *NSAIDs*, nonsteroidal antiinflammatory drugs; *NCC*, sodium chloride cotransporter; *DRC,* direct renin concentration.

TABLE 96.3 Factors Causing False-Negative Aldosterone-To-Renin Ratios

	Effect on Aldosterone	Effect on Renin	Mechanism
Diuretics (K^+ wasting or sparing)	↑↔	↑↑	Volume contraction and sympathetic nervous system stimulation stimulate renin Fall in plasma K^+ with K^+ wasting diuretics lowers aldosterone
ACE inhibitors	↓	↑↑	Reduced production of angiotensin II relieves negative feedback on JG cells, leading to marked increase in renin while also reducing angiotensin II stimulation of aldosterone production by ZG cells
ARBs	↓	↑↑	Blockade of angiotensin II receptors relieves negative feedback on JG cells, leading to marked increase in renin while also reducing angiotensin II stimulation of aldosterone production by ZG cells
Dihydropyridine CCBs	↔↑	↑	Reflex sympathetic stimulation as BP falls, natriuretic effects, and direct stimulation of calcium-dependent renin regulatory pathways Interference with aldosterone biosynthesis by blocking intracellular calcium-dependent steps
SSRIs	↑	↑↑	Uncertain—serotonin may stimulate renin via the 5-HT_2 subtype of 5-HT receptors
Pregnancy	↑	↑↑	Progesterone induces natriuresis, which stimulates renin and aldosterone
Low dietary Na^+ Vomiting and diarrhea	↑	↑↑	Volume contraction and sympathetic nervous system stimulation stimulate renin
Malignant hypertension Concomitant renovascular hypertension	↑	↑↑	Intrarenal ischemia leads to renin production
Hypokalemia	↓	↔↑	Reduced stimulation of aldosterone production

ACE, Angiotensin-converting enzyme; *ARB*, angiotensin II receptor blocker; *ZG*, zona glomerulosa; *JG*, juxtaglomerular; *CCB*, calcium channel blocker; *SSRI*, selective serotonin receptor inhibitor; *BP,* blood pressure.

suppression of plasma aldosterone were reported to be less than 162 pmol/L if measured by mass spectroscopy[128] and less than 171 pmol/L (but with a grey zone up to 217 pmol/L) if measured by chemiluminescence immunoassay.[109]

Unlike the above approaches, the captopril challenge test does not involve salt loading, but instead measures aldosterone and renin responses to 25 to 50 mg oral captopril, an ACE inhibitor, administered after sitting or standing for at least 1 h.[129] Blood samples are drawn basally and at 1 or 2 h after challenge, with the patient remaining seated throughout. In subjects without PA, plasma aldosterone is suppressed (>30%) and PRA stimulated by captopril, and, as a result, the ARR falls. In patients with PA aldosterone fails to suppress, PRA remains suppressed, and the ARR remains elevated. In one commonly used protocol, the cutoff for normal suppression of plasma aldosterone is less than 8.5 ng/dL (240 pmol/L) and for the ARR is less than 30 (with aldosterone expressed as ng/dL and PRA as ng/mL/h) 2 h after receiving 50 mg of captopril. Because it does not involve salt loading, the captopril challenge testing avoids the potential for inducing fluid overload in patients at risk because of compromised cardiac or renal function and hypokalemia. However, it has been reported to have poor discriminatory power[130,131] and may be associated with symptomatic hypotension due to the blood pressure-lowering effect of captopril in upright patients.

Because of the enhanced risk of potentially dangerous fluid overload, it may be necessary to avoid confirmatory testing involving salt loading in patients with severe hypertension or compromised cardiac status (e.g., reduced left ventricular systolic function or marked left ventricular hypertrophy) or renal dysfunction. Alternatively, consideration may be given to either a period of medical treatment with an agent that blocks aldosterone action as an attempt to establish better hypertension control and improve cardiac function in order to reduce the risk of confirmatory testing to a more acceptable level, or to proceeding directly to subtype differentiation (including AVS).

Confirmatory testing (followed, if positive by AVS) could also be avoided in favor of an empiric trial of medical treatment for PA in patients for whom unilateral adrenalectomy is not likely to be a viable treatment option, either because they are poor candidates for surgery or do not desire surgical intervention.

Subtype Differentiation. As described earlier in this chapter, the availability of immunohistochemical staining using antibodies directed against CYP11B2 has enabled investigators to identify the true source of aldosterone excess within adrenals removed from patients with PA, and this in turn has led to the realization that the morphology associated with PA is diverse and far more complex than previously suspected. From a clinical standpoint, however, rather than attempting to distinguish the many pathological variants from each other, subtype differentiation aims to assist selection of the optimal management approach. This is achieved by:

- genetic testing when a familial form of PA is suspected;
- imaging to enable detection of large adrenal lesions that may warrant consideration of removal because of their malignant potential; and
- determining whether autonomous aldosterone production is unilateral (confined to one adrenal), and therefore potentially curable by unilateral adrenalectomy, or bilateral, in which case management usually involves treatment with medications that antagonize aldosterone action.

Genetic testing for FH-I involves the use of either Southern blotting or a faster and less expensive PCR-based method to detect the causative hybrid *CYP11B1*/*CYP11B2* mutation within peripheral blood DNA.[132,133] The principal reasons for identifying individuals with this subtype of PA are that (1) patients with FH-I demonstrate excellent clinical responses to glucocorticoid medications given in small doses that do not cause Cushingoid side effects, making them the treatment of choice for this (but no other) subtype of PA; and (2) it heralds the need for genetic testing of other family members to detect additional individuals with FH-I similarly at risk of hypertension and early death from hemorrhagic stroke, but who will also benefit greatly from specific glucocorticoid treatment. The recommendation by the Endocrine Society is to test patients with onset of confirmed PA earlier than at 20 years of age and those who have a family history of PA or of strokes at young age (<40 years).[22] The case for screening for germline mutations in *CLCN2* (causing FH-II), *KCNJ5* (FH-III), and *CACNA1H* (FH-IV) is not as strong as that for FH-I, being even rarer than hybrid gene mutations and (unlike FH-I) with no specific form of treatment yet available. At present, given that early age of onset of hypertension is almost universal among these individuals, it would seem prudent to restrict genetic testing for these mutations to very young patients with PA. As with FH-I, genetic testing for these mutations identifies individuals whose family members should be genetically screened, thereby facilitating timely institution of specific medical or surgical treatment in those who test positive.

Adrenal imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is essential for the detection of larger (e.g., >2.5 cm) mass lesions that have greater potential for malignant behavior and may warrant consideration for removal on that basis alone, or at the very least deserve careful follow-up.

While the above facets of subtype differentiation are relatively straightforward, distinguishing unilateral from bilateral PA is much more complex. It is nevertheless an important aspect of the diagnostic workup of PA, as the clinical responses to unilateral adrenalectomy in patients with unilateral forms of PA are generally quite marked, with cure of hypertension achieved in 40% to 70%, and greater reductions in pill burden, better cardiovascular outcomes, and greater improvements in quality of life compared with patients with PA treated medically with drugs that antagonize aldosterone action.[99,101,134,135] For several decades, AVS has served as the mainstay of differentiating these two PA subtypes, as it is the most reliable. It is also the most invasive and expensive and requires considerable expertise. As a result, many alternative approaches have been explored, but with inefficient reliability to replace AVS. Although unilateral PA (including APA) is generally associated with more florid features of PA than bilateral, there is considerable overlap, and clinical prediction algorithms that have incorporated such parameters as plasma sodium and potassium, total carbon dioxide, aldosterone, renin, and the ARR have shown variable (and not very reproducible) performance characteristics.[136] Adrenal imaging by CT or MRI frequently misses APAs and can be frankly misleading by detecting nonfunctioning adrenal lesions.[97,137] Scintigraphy lacks sufficient resolution to detect smaller APAs. Posture stimulation studies (comparing recumbent with upright plasma aldosterone concentrations) more often showed posture unresponsiveness and plasma or urinary levels of "hybrid steroids" (18-hydroxy- and 18-oxocortisol) are more often elevated in patients with APA compared with bilateral PA,[138] but again, considerable overlap exists. The diversity in phenotype among patients with APA regarding these two parameters may in part be genetically determined: patients with APAs associated with somatic *KCNJ5* mutations usually show posture-unresponsiveness and elevated hybrid steroid levels, whereas the reverse holds true for those with somatic *CACNA1D* (and other) mutations.[139] Despite the shortcomings of these alternatives to AVS, they can nevertheless provide useful ancillary information that may help in the decision-making process, especially when AVS has been declined for some reason or results have been inconclusive (e.g., because of failure to cannulate one or both adrenal veins). For example, the presence of an obvious unilateral mass lesion on CT in a young patients with florid, hypokalemic, posture-unresponsive PA and elevated hybrid steroid levels (if available) would make APA highly likely. Nuclear imaging using positron emission tomography–CT with (11)C-metomidate has been reported to be a viable alternative or adjunct to AVS in difficult cases.[140,141] However, the short half-life and lack of specificity of the isotope for CYP11B2 (being a ligand also for CYP11B1) limits the current widespread application and reliability of this technique, though alternatives are being investigated.

The Endocrine Society guideline[22] recommends that AVS be offered to all patients with PA who desire adrenalectomy and for whom surgery is not contraindicated, regardless of biochemical or CT findings. Some investigators advocate performing AVS in the morning following overnight recumbency in order to avoid the confounding effects of changes in posture on aldosterone concentrations and to capitalize on the higher endogenous ACTH levels (compared with later in the day), which ensure that samples are collected during maximal ACTH-induced stimulation of aldosterone production (unless stimulation with exogenous ACTH is employed).[124] The likelihood of achieving successful cannulation of the adrenal veins is maximized when CT scanning is performed prior to AVS to assist in localizing the adrenal veins,[142] a radiologist highly skilled in AVS performs the procedure, at least two samples are collected from each side, and rapid point-of care cortisol testing is used to confirm correct catheter placement. Examination of the ratio or "gradient" between adrenal and peripheral venous cortisol concentrations permits confirmation (or otherwise) of cannulation success, with gradients of at least two or three (or at least five if exogenous ACTH stimulation is used) most commonly used to indicate adequacy of AVS. The right adrenal vein tends to be harder to cannulate than the left because it is usually smaller and shorter and, unlike the left adrenal vein, usually empties into the inferior vena cava rather than the renal vein.[143] Calculating the aldosterone/cortisol ratio for each adrenal and peripheral venous sample corrects for differences in dilution with nonadrenal venous blood. Criteria for lateralization vary widely from one institution to another,[144] with some comparing adrenal venous aldosterone/cortisol ratios on each side with the simultaneous peripheral venous ratio (with lateralization defined as a the ratio being at least 2.5 times peripheral on the affected side and no higher than peripheral on the other side), while others rely on the comparison of aldosterone/cortisol ratios on one side versus the other (the so-called "lateralization index"), with lateralization defined as the ratio on the higher side being at least two to four times, depending on the center, that on the lower side. Several groups employ exogenous ACTH stimulation during AVS to (1) maximize adrenal/peripheral venous cortisol gradients, (2) reduce fluctuations in steroid secretion during AVS and (3) stimulate aldosterone production by APAs, and thus avoid sampling during a period of secretion "quiescence."[144,145] The risk of adrenal hemorrhage associated with AVS is low (less than 2% of all procedures) in experienced hands.[142]

Recent advances and changes in thinking regarding AVS have included: (1) "superselective" sampling of branch adrenal veins, enabling more precise localization of the source (or sources) of aldosterone excess within a gland, which is particularly relevant in situations where subtotal adrenalectomy is considered desirable (for example, if the patient has only one functioning adrenal or is thought to have bilateral APAs)[146]; (2) the development of point-of-care plasma cortisol measurement, which permits semiquantitative determination of adrenal venous cortisol levels, and thus an assessment of the success or otherwise of cannulation within minutes of collection[147]; and (3) normalization of aldosterone levels with hormones other than cortisol, either to improve apparent rates of successful cannulation or where the patient is suspected of having an adrenal tumor that is concomitantly autonomously secreting both cortisol and aldosterone.[107,148]

KEY POINTS

- Detection and diagnostic workup for primary aldosteronism involves screening by measurement of the plasma aldosterone/renin ratio, confirmatory suppression testing, and determining the subtype by genetic testing (when familial forms are suspected), adrenal imaging, and adrenal venous sampling to differentiate unilateral from bilateral forms.

TREATMENT

Early recognition of PA is paramount to facilitate the opportunity to initiate targeted treatments. The objective of targeted treatments is to reduce the risk for incident cardiovascular and kidney disease. The traditional dogma for decades has been to prescribe surgical adrenalectomy or lifelong MR antagonist therapy, depending on the subtype of PA. It is important to note that there have been no robust, randomized, and controlled trials to evaluate the validity of this dogma or the comparative efficacy of these options. For example, whether MR antagonists are superior to conventional (nontargeted) antihypertensive medications, or whether surgical adrenalectomy is superior to MR antagonist therapy, has not been validated in prospective and controlled studies. Rather, these approaches have been recommended based on their pathophysiologic mechanisms of action, their provenance, and supportive observational human studies.

Herein, treatments for PA are discussed in two groupings: surgical adrenalectomy and medical therapy. Surgical adrenalectomy may involve curative unilateral adrenalectomy, noncurative unilateral adrenalectomy, and bilateral adrenalectomy. Medical therapy may involve MR antagonists, dietary sodium restriction, and epithelial sodium channel inhibitors.

Surgical Adrenalectomy. The treatment of choice for unilateral PA is curative unilateral laparoscopic adrenalectomy when patients are willing and able to undergo this operation. Laparoscopic and retroperitoneoscopic approaches are the gold standard and allow surgical resection with a minimally invasive approach. The unique attribute of adrenalectomy for unilateral PA is the opportunity to completely cure the disease by eliminating the source of inappropriate aldosterone production, curing hypokalemia, and either curing hypertension or dramatically improving blood pressure control.

The definition of cure following unilateral adrenalectomy has been defined by the Primary Aldosteronism Surgery Outcomes (PASO) study,[149] where a "complete clinical cure" was defined as postoperative normalization of blood pressure without the use of any antihypertensive medication use. A "complete biochemical cure" was defined by normalization of serum potassium without the need for supplements, along with a decrease in circulating aldosterone and/or an increase in renin such that there was normalization of the ARR. Notably, the PASO study highlighted that, whereas the majority of patients achieve a biochemical cure following adrenalectomy for unilateral PA (94%), only a minority (37%) of patients achieve a complete clinical cure, in part owing to the vasculopathy induced by longstanding hypertension and aldosteronism.

Biochemical changes induced by curative unilateral adrenalectomy include normalization of serum potassium, an increase in serum creatinine and decrease in estimated glomerular filtration rate, a dramatic decline in plasma aldosterone, an increase in or normalization of renin (from suppressed to unsuppressed/detectable), and consequently a decline in the ARR.[150] These biochemical changes all reflect the expected physiology induced by removing inappropriate and excessive aldosterone production: as intravascular volume contracts, renin and angiotensin II increase, glomerular hyperfiltration decreases, delivery of sodium ion to the distal nephron decreases, and excretion of urinary potassium and hydrogen ion decrease. The increase in serum creatinine following curative adrenalectomy is usually not a marker of kidney injury, but rather represents a reflection of the true underlying kidney function once hyperfiltration is corrected. In this regard, many patients with PA may be found to have some degree of chronic kidney disease postadrenalectomy that was previously not recognized.

The clinical changes induced by curative adrenalectomy may include a cure of hypertension, reductions in cardiometabolic risk, and reduction in the risk of death. Cure of hypertension is observed in the minority of cases and more commonly among younger patients with a shorter duration of hypertension. More commonly, hypertension is not cured, but blood pressure control is improved and/or the number of antihypertensive medications required is decreased.

Early observational data from a small sample size of 54 patients comparing long-term cardiovascular outcomes between PA patients treated with adrenalectomy, PA patients treated with MR antagonist therapy, and a comparator group of patients with essential hypertension suggested no difference in long-term cardiovascular risk among these groups.[151] However, more recent observational data from large studies[152] have shown that, despite similar blood pressure control between the groups, patients with PA treated with MR antagonists had a 3-fold higher risk for incident cardiovascular events compared with patients with PA treated with curative adrenalectomy and a 2-fold higher risk compared with patients with essential hypertension. In contrast, patients with PA treated with curative adrenalectomy had a 40% lower risk for incident cardiovascular events compared with patients with essential hypertension.[152-154] However, when MR antagonist therapy resulted in a substantial increase in renin activity, the risk for incident cardiovascular events was observed to be no different than comparable patients with essential hypertension and similar to those who underwent curative adrenalectomy. These observational findings underscore the efficacy of surgical adrenalectomy, but also suggest that, when MR antagonist therapy can be titrated to achieve a similar physiology to adrenalectomy, adverse outcome rates may approximate, but not quite capitulate, the effects of adrenalectomy.[150]

Curative adrenalectomy in PA has been shown to have a beneficial effect in terms of preventing incident atrial fibrillation compared with MR antagonist therapy and in preventing incident diabetes when compared to essential hypertension. Several studies have shown that curative adrenalectomy is associated with a preservation of kidney function when compared to MR antagonist therapy, where declines in glomerular filtration rate and the incidence of chronic kidney disease are greater. Both curative adrenalectomy and medical therapy have been shown to improve quality of life; however, the improvements in quality-of-life metrics following curative adrenalectomy have been more substantial.[150]

Although surgical adrenalectomy is most commonly recommended as a curative procedure for unilateral PA, there is also evidence to support the efficacy of noncurative unilateral adrenalectomy in bilateral PA. Importantly, there is no high-grade clinical trial evidence comparing noncurative unilateral adrenalectomy with lifelong MR antagonist therapy in bilateral PA; rather, supportive evidence stems from observational studies and anecdotal patient series. In a case series of 12 patients who underwent noncurative unilateral adrenalectomy for bilateral PA, patients who had noncurative adrenalectomy had a substantial and durable reduction in blood pressure, a modest decrease in aldosterone levels, a substantial increase in renin that paralleled the rise in renin seen in those who underwent curative unilateral adrenalectomy, and near-normalization of serum potassium.[155] In a larger study of 51 patients who underwent noncurative adrenalectomy for bilateral PA, the operation cured hypertension in 15% of patients, improved blood pressure control in 40%, decreased aldosterone levels, substantially increased renin levels (and consequently decreased the ARR), normalized serum potassium, and increased serum creatinine.[156] Notably, the adrenalectomy in this series was performed to target the morphologically larger adrenal and/or where adrenal venous sampling suggested greater lateralization. These findings, in combination with anecdotal clinical experiences, suggest that unilateral noncurative adrenalectomy for bilateral PA could be considered as an adjunct method to induce improvements in pathophysiology and clinical parameters in selected patients, particularly when guided by some degree of lateralization and/or greater morphologic abnormalities. In some centers, the use of super-selective adrenal venous sampling to detect specific foci of aldosterone production, as well as thermal and arterial ablations, have also been shown to be effective targeted therapies.

Bilateral adrenalectomy for bilateral PA is rarely employed for sporadic cases of PA, and is not recommended or supported by any reliable studies. Because bilateral adrenalectomy can cure the aldosteronism, it may be used as an option in extreme instances where unilateral adrenalectomy and/or medical therapy are unable to improve clinical and biochemical parameters, and when the risk for incident cardiometabolic disease is considered to be more severe than the risk for lifelong primary adrenal insufficiency. Detailed discussions regarding the risks, benefits, and ethics of such a decision should occur in conjunction with an experienced endocrinologist with knowledge in managing adrenal insufficiency and PA.

In summary, surgical adrenalectomy is effective when utilized to unilateral PA, but sometimes also when used to attenuate the severity of the excess aldosterone production in bilateral PA. The hallmark characteristics suggestive of efficacy include improvements (or cure) of hypertension, reductions in aldosterone and increases in renin (such that the ARR is markedly reduced), normalization of serum potassium, and increases in serum creatinine indicative of a resolution in glomerular hyperfiltration. These features are associated with a reduction in the incident risk for cardiometabolic disease and death.

Medical Therapy. Medical therapy, here defined as any nonsurgical therapy, is the approach of choice when PA is deemed to be bilateral in origin by adrenal venous sampling, or when patients are unable or unwilling to undergo surgical adrenalectomy. Prior to initiating targeted MR antagonists, the critical importance of dietary sodium restriction should be underscored for patients, as it is a foundational intervention for all patients with hypertension. The efficacy of dietary sodium restriction for PA is high, and this is particularly true when combined with MR antagonists. Sodium is the substrate that fuels the pathophysiology of PA. Dietary sodium restriction results in reductions in effective arterial circulating volume, decreases in glomerular filtration, reductions in distal nephron sodium delivery, and consequently reductions in MR-mediated sodium reabsorption and potassium and hydrogen ion excretion. Most patients in industrialized societies consume more than 150 to 200 mmol of sodium per day. In contrast, the American Heart Association recommends consuming less than 65 mmol of sodium per day for patients with hypertension. In one study, restricting dietary sodium intake to less than 50 mmol per day in patients with PA dramatically lowered blood pressure, substantially increased renin, and normalized the ARR in over 50% of participants.[157] While the efficacy of dietary sodium restriction is established, the ability for most patients to adhere to these degrees of sodium restriction is a major challenge. Therefore, involving professional dieticians and nutrition support can be a valuable adjunct to pharmacologic therapy.

In addition to dietary sodium restriction, MR antagonists are the mainstay of pharmacologic medical therapy. By blocking the MR, MR antagonists reduce sodium reabsorption and volume expansion, and consequently potassium and hydrogen ion excretion decline. In this manner, MR antagonists are capable of improving blood pressure, hypokalemia, and alkalosis. The main risk of MR antagonist therapy is hyperkalemia, which is more likely to occur when patients have concomitant reductions in glomerular filtration rate or use renin-angiotensin-aldosterone system inhibitors. Spironolactone and eplerenone are the most well-known MR antagonists; both have a steroidal structure that permits competitive inhibition of aldosterone. Spironolactone is generally regarded as the first choice, whereas eplerenone should be considered for patients who cannot tolerate spironolactone. Spironolactone is approximately twice as potent as eplerenone and also inhibits the androgen receptor and activates the progesterone receptor; therefore, the most common adverse reaction leading to intolerance is gynecomastia in adult men, with menstrual irregularities in women being less common. The starting dose of spironolactone is usually 12.5 to 25 mg daily, but it can be titrated up to 200 mg daily. Eplerenone is usually initiated at 25 to 50 mg daily and can be titrated up to 200 to 400 mg daily. Beyond these conventional MR antagonists, new agents in development include finerenone and esaxerenone. Both finerenone and esaxerenone are nonsteroidal MR antagonists that been shown to reduce the progression of kidney disease. Esaxerenone has shown efficacy in lowering blood pressure, and finerenone is undergoing further study in heart failure.

It should be noted that epithelial sodium channel antagonists, such as amiloride and triamterene, are also effective for blood pressure and potassium control in PA; however, these agents also carry the risk for hyperkalemia when kidney function is impaired, and further, they do not block the MR. Therefore, whether long-term use of amiloride can mitigate MR-mediated cardiovascular disease beyond blood pressure control remains unknown.

The primary goals of medical therapy (dietary sodium restriction in combination with MR antagonists and/or epithelial sodium channel inhibitors) are normalization of blood pressure and serum potassium. The secondary goals are to optimize biomarkers associated with a decreased risk for incident cardiometabolic adverse outcomes. MR antagonists should be titrated to adequately block the renal and extrarenal MR. Optimized medical therapy is ideally defined as normal blood pressure, normal or high-normal serum potassium, and an increase in renin activity or concentration.[150] The achievement of these clinical and biochemical milestones is associated with similar cardiovascular risk reduction achieved by surgical adrenalectomy. When MR antagonist therapy is unable to optimize these clinical and biochemical parameters, amiloride can be added, or noncurative unilateral adrenalectomy considered.

KEY POINTS

- There are multiple modalities to effectively treat primary aldosteronism. When possible, curative surgical adrenalectomy is the preferred method to improve blood pressure and risk for future cardiovascular events. Alternatively, medical therapy that combines dietary sodium restriction and mineralocorticoid receptor antagonists can also impart similar reductions in blood pressure and cardiovascular risk. In some select cases, the use of epithelial sodium channel inhibitors or noncurative unilateral adrenalectomy may be beneficial.

INTRODUCTION

KEY POINTS

- Cushing syndrome is a rare disease, characterized by chronic and excessive exposure to glucocorticoids.
- Cushing syndrome is a prototype of metabolic syndrome and results in high morbidity and mortality if not treated.
- During the last few years there have been improvements in our knowledge of the molecular mechanisms involved in the pathogenesis of adrenal Cushing syndrome.

Cushing syndrome (CS) is a rare endocrine condition, firstly described in 1912 by Harvey Cushing,[1] and is characterized by chronic and excessive exposure to glucocorticoids. CS can include significant morbidity and even mortality (if untreated), and its diagnosis and treatment can be challenging.[2] In humans, cortisol is the primary active glucocorticoid produced by the adrenal cortex under the control of pituitary adrenocorticotropic hormone (ACTH), and its actions include mobilization of fats, proteins, and carbohydrates. CS can be secondary to chronic stimulation of the adrenal cortex by ACTH secreted by a pituitary or ectopic ACTH-secreting tumor, or by a primary adrenal dysregulation. In the latter case, the causative adrenal lesions are independent of physiological regulation by pituitary ACTH, as the activity of the pituitary corticotroph cells is typically suppressed by glucocorticoid-mediated negative feedback; this can be classified as "adrenal Cushing." The adrenal lesions responsible for adrenal Cushing can be unilateral or bilateral, and can represent benign or malignant disease.

This chapter will discuss clinical aspects of the diagnosis and management of the various causes of adrenal Cushing and recent advances in our understanding of their molecular genetics.

EPIDEMIOLOGY

KEY POINTS

- Adrenal Cushing syndrome accounts for approximately 20%–25% of all cases of endogenous Cushing syndrome, second only to benign and malignant adrenal disorders.
- Adrenocortical tumors are frequent in the general population (3%–10% of adults), but the subset responsible for overt Cushing are rare, with the incidence being estimated at approximately 1.5/million/year, with a higher prevalence in females.

CS is a rare disease, with an estimated incidence ranging between 1 to 5 per million each year,[3] although the estimations, as is the case for many rare diseases, are imprecise. Approximately 20% to 25% of endogenous CS cases are secondary to adrenal gland disorders including adenomas, carcinomas, and nodular hyperplasias (which may be macronodular and micronodular, based on nodules size [>1 cm or <1 cm in diameter, respectively]).[4-6] The specific incidence of adrenal Cushing has rarely been investigated but may be around 1.5 per million per year.[7] On the other hand, adrenal tumors are quite common, affecting 3% to 10% of the human population. According to autopsy data, one in 10 adults (over the age of 50 years) has at least one adrenocortical nodule measuring up to 1 cm.[8] The majority are small benign or nonoversecreting adrenocortical adenomas (ACAs), but investigation of incidentalomas suggests that a proportion could produce mild cortisol excess and be related to typical features of the metabolic syndrome. The most prevalent somatic molecular defect alters the protein kinase A catalytic alpha-subunit, primarily in adenomas associated with overt CS. Interestingly, no such mutations occur in patients with mild cortisol secretion or with other adrenocortical tumors (ACTs).[5] By contrast, adrenocortical carcinoma (ACC) is a rare malignant disease that accounts for 0.05% to 0.2% of all human cancers, with an estimated incidence of 0.5 to 2 per million per year in adults.[9] The frequency is even lower in children, with only approximately 25 new cases of ACC occurring in the United States each year. Nevertheless, the incidence of pediatric ACT is remarkably high in South and Southeast Brazil, where it is estimated to be 15 times greater than the worldwide incidence, owing to a high frequency of a germline-specific pathogenic variant (p.R337H) of the *TP53* tumor suppressor gene.[10-12] In addition to the age of onset, pediatric ACT differs from adult tumors in many other ways.[13] Women are three times more likely to have either benign or malignant adrenal tumor, and approximately four to five times more likely to have CS associated with an adrenal tumor, but the reasons for this preponderance in women are unknown.[14-17]

All other causes of CS are extremely rare, including CS due to either primary macronodular adrenal hyperplasia (PMAH) or primary micronodular adrenal hyperplasia,[5] also known as primary bilateral macronodular adrenal hyperplasia (PBMAH) and previously called ACTH-independent macronodular adrenal hyperplasia (AIMAH), massive macronodular adrenocortical disease, and giant macronodular adrenal hyperplasia, among other names, is classically considered to represent less than 1% of cases of endogenous CS.[18-21] However, currently PMAH is often diagnosed after investigation of patients with bilateral adrenal incidentalomas associated with mild autonomous cortisol excess; therefore, the true prevalence is likely higher than previously thought.[22] PMAH presents a bimodal age distribution with a slightly female prevalence and a rare subset presenting in the first years of life, particularly in patients with the McCune–Albright syndrome.[23] Most patients with PMAH present in their fifth and sixth decades. The disease can be sporadic or associated with genetic syndromes (multiple endocrine neoplasia type 1 syndrome, familial adenomatous polyposis and hereditary leiomyomatosis, and renal cell cancer disorder) and more frequently occurs in familial form than earlier supposed, mostly due to germline *ARMC5* pathogenic variants.[24,25] Of the micronodular variety, primary pigmented nodular adrenocortical disease (PPNAD) is the most common endocrine manifestation in Carney complex (CNC), a rare autosomal dominant multiple endocrine neoplasia.[1] In approximately 60% of young patients with CNC, PPNAD causes adrenal Cushing, and more than 80% of these patients have germline pathogenic variants in *PRKAR1A*.[26]

Mortality from untreated adrenal CS is high, up to 2-fold that of the general population, mostly due to cardiovascular and cerebrovascular events and infections. After removal of a benign adenoma, survival is comparable to that of the general population; nevertheless, increased risk of infections and cardiovascular events appear to persist.[27] Mortality from malignant adrenocortical cancer is high for stage 3 and 4 of the disease and slightly better for patients with localized disease.[27] In CS due to PPNAD as part of the familial multiple endocrine neoplasia CNC, extraendocrine manifestations such as cardiac myxomas contribute to the excess mortality.[26]

PATHOPHYSIOLOGY—MOLECULAR GENETICS AND ANIMAL MODELS

KEY POINTS

- Mutations in regulatory members of the protein kinase A (PKA) signaling pathway (*PRKAR1A, PRKACA,* and *PDE* genes) lead to Cushing syndrome.
- *ARMC5* mutations are responsible for approximately 40% of primary macronodular adrenal hyperplasias, but the molecular relationship between its inactivation and cortisol hypersecretion remains unclear.
- Activating mutations in *CTNNB1*, which encodes β-catenin, are the second most frequent alteration identified in cortisol-producing adenomas (after *PRKACA* mutations).
- The crucial role of the opposition between PKA and Wnt/β-catenin pathway in maintaining normal adrenocortical zonation has been demonstrated using animal models.

The main molecular characteristic of a cortisol-producing adrenocortical lesion is abnormal activation of protein kinase A (PKA) signaling, which naturally controls cortisol secretion in response to ACTH (Fig. 97.1). To date, various genetic or molecular causes of this activation have been identified, and, interestingly, the adrenocortical features differ depending on the genetic/molecular origin of this activation. We will discuss herein: 1) the genetic/molecular alterations discovered in the different forms of ACTs and hyperplasias; 2) the advances made in our understanding of the adrenocortical physiopathology through the characterization of mouse models.

Molecular and Genetic Causes of Cortisol-Producing Adrenocortical Lesions

The important advances made in "omics" approaches have been great assets in order to discover the molecular alterations that are potentially responsible for cortisol-producing adrenocortical lesions. Interestingly, most of the genetic and molecular alterations identified in both cortisol-producing adenomas (CPAs) and hyperplasias affect regulatory members of the PKA pathway, which is consistent with the central role played by PKA in the regulation of cortisol secretion (Table 97.1). Although genetic alterations are mostly specific to a form of cortisol-producing adrenocortical lesion, some genes are, for instance, altered in both macronodular and micronodular hyperplasias. The known relationships between genetic/molecular alterations identified in patients and their adrenocortical presentation will be discussed herein.

Bilateral Adrenocortical Hyperplasia. Inactivating germline mutations affecting *PDE11A* and *PDE8B* have been identified in CS patients.[28] Both genes encode for phosphodiesterases (PDEs) that hydrolyze cyclic adenosine monophosphate (cAMP) and therefore inhibit the PKA pathway. Interestingly, these genetic alterations have been identified in PMAH, PPNAD, and ACA suggesting that they are directly involved in cortisol hypersecretion, probably through at least partial loss of their inhibitory effect on the cAMP/PKA pathway, which is abnormally activated as part of the different adrenocortical causes of CS.[28] Consistent with this, treatment of the human adrenocortical cell line H295 with a PDE11A inhibitor leads to an increase in cAMP and cortisol secretion. Interestingly, PDE alterations have been identified in association with others genetic defects, supporting the hypothesis that PDE mutations may be a secondary event that amplifies activation of cAMP/PKA signaling, resulting in hypercortisolism.[29]

Primary Macronodular Adrenal Hyperplasia. Mutations in the melanocortin 2 receptor (*MC2R*) gene encoding the ACTH receptor have been described in few cases of PMAH. These mutations lead to activation of the receptor, which increases cytosolic cAMP levels, resulting in release of the catalytic subunit of PKA and therefore inducing steroidogenesis and cortisol secretion (Fig. 97.1). Although MC2R-activating mutations are a rare cause of PMAH, the illegitimate expression of ectopic or eutopic membrane G protein-coupled receptors (GPCRs) mimicking ACTH response under the control of other hormones has for years been considered the main molecular characteristic of PMAH compared with other cortisol-producing tumors. Indeed, aberrant expression in cortisol-producing adrenocortical cells of β-adrenergic receptors (β-AR), vasopressin (V2–V3-vasopressin receptor), serotonin (5-HT7 receptor), and glucose-dependent insulinotropic peptide (GIPR) have been described in PMAH. In some others cases, the hypersecretion is due to altered expression of eutopic receptors like vasopressin (V1-vasopressin receptor), luteinizing hormone/human chorionic gonadotropin (LH/hCG), serotonin (5-HT4 receptor), and leptin (LEPR).[29] As the cause of this abnormal GPCR expression is mainly unknown, it is unclear whether this molecular alteration is a primary

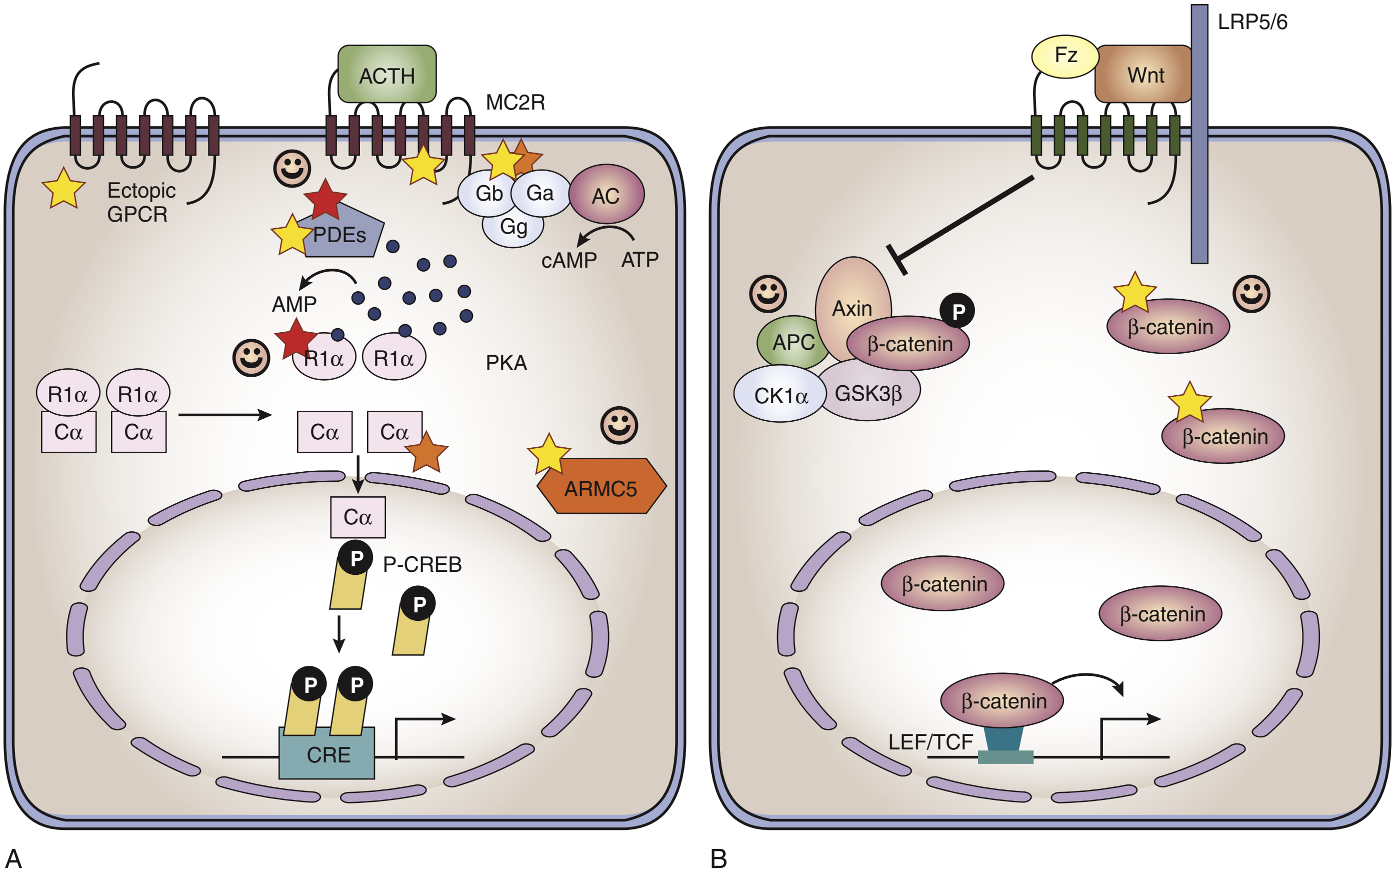

Figure 97.1 **Overview of the most frequently altered signaling pathways in cortisol producing adrenocortical lesions. A,** Protein kinase A (PKA) signaling. In response to adrenocorticotropic hormone binding to melanocortin 2 receptor, adenylate cyclase (AC) increases the cyclic adenosine monophosphate (cAMP) level after activation through Gsα. cAMP then binds to the regulatory (R1α) subunits of PKA that dissociate from the catalytic subunit (Cα). Free calcium phosphorylates cAMP response element binding protein (CREB), which, in turn, regulates the expression of steroidogenic genes. Stars indicate the elements that have been observed to be mutated in primary pigmented nodular adrenocortical disease *(red)*, primary macronodular adrenal hyperplasia (PMAH) *(yellow)*, and cortisol-producing adenoma (CPA) *(orange)*. The smiley face indicates the genetic alterations that have been mimicked in mouse models. **B,** In absence of Wnt ligand, β-catenin is phosphorylated by a destruction complex composed of GSK3β, APC, CK1α, and axin. Phosphorylated β-catenin is then degraded by the proteosome. However, in presence of ligand, the destruction complex is inhibited, allowing the nucleocytoplasmic accumulation of β-catenin, which acts as a cotranscriptional activator and activates genes involved in cell proliferation. The stars highlight the genetic alterations that have been found in PMAH *(yellow)* and CPA *(orange)*.

or a secondary event in PMAH. However, it has been reported that GIPR overexpression is due in a few cases to duplication of chromosome 19q13.32, including the *GIPR* gene.[30]

The bilateral presentation of the macronodules that characterizes PMAH suggests the presence of a germline genetic predisposition. Accordingly, PMAH cases have been reported in patients presenting familial syndromes such as multiple endocrine neoplasia type 1, familial adenomatous polyposis, and hereditary leiomyomatosis and renal cancer syndrome. The presence of PMAH in these patients suggest that mutations in the menin 1 (*MEN1*), adenomatous polyposis coli (*APC*) or fumarate hydratase (*FH*) genes causing these syndromes could lead to adrenocortical hyperplasia, but these alterations only explain a small subset of PMAH cases.[29] Therefore, in order to identify more frequent cause of PMAH development, blood and tumor DNA from 33 PMAH patients have been analyzed using different genomic approaches. Interestingly, the most frequent somatic chromosome alteration and mutation are both located at 16p. Indeed, whereas a loss of heterozygosity at 16p was found in eight out of 33 patient tumors (24%), mutations in a gene called armadillo repeat-containing protein 5 (*ARMC5*) located at 16p11.2 was described in 18 out of 33 patients (55%).[31] Since its initial discovery in 2013, genotyping of *ARMC5* has been performed in several PMAH cohorts in centers worldwide, and it is now estimated that germline *ARMC5* mutations are responsible for approximately 40% of PMAH cases.[32] Interestingly, most *ARMC5* mutations are frameshift or nonsense mutations, leading most probably to a loss of *ARMC5* function, and its germline defect is associated with somatic mutations or loss of heterozygosity in the nodules' DNA.[29] Altogether, these observations support a tumor suppressor role of *ARMC5* in adrenocortical cells. However, as ARMC5 function is still unclear, one important remaining challenge is to determine if germline missense *ARMC5* variants are deleterious to its function. This is especially important, as several familial form of PMAH due to *ARMC5* mutations have been reported.[32] Interestingly, although adrenocortical size and hormonal phenotype vary among members of *ARMC5* families, *ARMC5*-mutated patients have a particular clinical phenotype characterized by overt CS and an increase in adrenal size compared with PMAH patients without *ARMC5* defects. These observations suggest that loss of *ARMC5* function drives the development

TABLE 97.1 Genetic Alterations Identified in Cortisol-Producing Bilateral Micronodular Hyperplasia (Primary Pigmented Nodular Adrenocortical Disease [PPNAD]), Cortisol-Producing Bilateral Macronodular Hyperplasia (Primary Macronodular Adrenal Hyperplasia [PMAH]), and Cortisol-Producing Adenoma (CPA)

Adrenocortical presentation	Genes	Chromosomal location	Genetic Event	Identified Mutations	Molecular Function	References
Reported in PPNAD and PMAH	*PDE8B*	5q13	Inactivating mutations	p.H305P in PPNAD and p.H391A in PMAH	Hydrolysis of cAMP, inhibition of PKA signaling	26
	PDE11A	2q31	Inactivating mutations	p.R307* in PPNAD	Hydrolysis of cAMP and cGMP, inhibition of PKA signaling	26
PMAH	*MC2R*	18p11	Activating mutations	-	ACTH receptor, activation of PKA signaling	
PMAH	*GNAS*	20q13	Postzygotic activating mutations	-	Ga subunit GTPase, activation of PKA signaling	
PMAH	*APC*	5q12-22	Inactivating mutations	-	Inhibition of Wnt/β-catenin pathway	
PMAH	*MEN1*	11q13	Inactivating mutations or deletion	-	Controls gene transcription and cell proliferation	
PMAH	*FH*	1q42	Inactivating mutations	-	Fumarate conversion to malate in Krebs cycle	
PMAH	*ARMC5*	16p11	Inactivating mutations	More than 50 deleterious mutations	Controls steroidogenesis and proliferation	30
PPNAD	*PRKAR1A*	17q24	Inactivating mutations or deletion	More than 100 mutations	Regulatory subunit of PKA, inhibition of PKA signaling	
PPNAD and PMAH	*PRKACA*	19p13	Duplication or triplication	-	Activation of PKA pathway	
CPA	*PRKACA*	19p13	Somatic activating mutations	Hot spot: p.L206R	Catalytic subunit α, activation of PKA signaling	32
CPA	*PRKACB*	1p31	Somatic activating mutations	p.S54L (one case)	Catalytic subunit β, activation of PKA signaling	37
CPA	*GNAS*	20q13	Somatic activating mutations	p.R201 substitutions	GTPase, activation of PKA pathway	38
CPA	*CTNNB1*	3p22	Somatic activating mutations	p.S45 substitutions	Activation of Wnt/β-catenin pathway	38

of a subtype of PMAH, even if the second *ARMC5* event occurring in adrenocortical nodules may affect the appearance of disease features as observed in relatives.

Primary Pigmented Nodular Adrenocortical Disease. As PPNAD is the main endocrine manifestation of a familial multiple neoplasia syndrome called CNC, it is mainly due to mutations in *PRKAR1A* that are found in the germline of more than 80% of CNC patients. To date, more than 100 mutations throughout the *PRKAR1A* gene have been identified in at least one CNC family. In most cases (83%), these mutations result in a premature stop codon.[33] Although there are three other regulatory subunits of PKA (PRKAR1B, PRKAR2A, PRKAR2B), this haploinsufficiency of the regulatory subunit R1α of PKA encoded by *PRKAR1A* gene is sufficient to increase the activity of the cAMP/PKA pathway, especially in adrenocortical cells. Moreover, based on the critical role of *PRKAR1A* in the regulation of PKA signaling, it is not surprising that somatic mutations or loss of the *PRKAR1A* locus have also been identified outside the CNC spectrum, in ACA and carcinoma.

More recently, genome-wide copy-number analysis has identified the presence of *PRKACA* copy number gain in three PPNAD patients with histological features similar to the those observed in patients with *PRKAR1A* haploinsufficiency.[34,35] As expected, knowing that *PRKACA* encodes the catalytic subunit α of PKA, functional analyses confirmed that these genetic alterations cause a gain of Cα function and therefore lead to activation of cAMP/PKA signaling. Indeed, *PRKACA* is overexpressed at both the transcript and protein level in the adrenocortical tissues from patients exhibiting *PRKACA* copy number gain. Interestingly, out of these three patients, two presented a *PRKACA* triplication associated with a younger age at diagnosis, suggesting a dose-dependent effect of *PRKACA* on the adrenocortical phenotype. Moreover, two related patients, mother and son, with *PRKACA* duplication have bilateral adrenocortical hyperplasia similar to PMAH and not PPNAD, suggesting that the adrenocortical presentation may vary depending on the *PRKACA* copy number gain.[35]

Unilateral Adrenocortical Adenoma. In 2014, exome sequencing data highlighted for the first time the presence of point mutations in *PRKACA,* which encodes the catalytic subunit α of PKA, in eight out of 10 CPAs.[34] Based on *PRKACA* genotyping data available from large cohorts of patients, the frequency of *PRKACA* mutations in CPA is now estimated to be between 27% and 40%, depending on the study.[36] Interestingly, somatic *PRKACA* mutations are highly specific to patients with overt Cushing caused by a unilateral adenoma, as they are very rare in other adrenocortical lesions.[34,36] These mutations are mainly found in a hot spot region of *PRKACA,* including the most frequent mutation, which is a missense mutation affecting amino acid 206 (p.L206R). *In silico* and *in vitro* functional analysis demonstrates that p.L206R alters the interaction between the catalytic and regulatory subunits, destabilizing the PKA holoenzyme and leading both to continuous activation of mutant Cα[34] and degradation of the regulatory subunit RIIβ (*PRKAR2B*) protein of PKA by a caspase 16-dependent mechanism.[37] Accordingly, CPAs with the *PRKACA* p.L260R mutation belong to the previously described group that exhibits lower RIIβ expression.[37,38]

In addition to p.L260R, six missense variants in *PRKACA* have been identified in at least one CPA, with all except one (p.E32V) located in the hot spot region at the interface with the regulatory subunit.[39] As previously observed for p.L260R, three others mutations (199_200insW, 200_201_insV, and S213R+insIILR) partially abolish the interaction with both RIα and RIIβ, whereas no clear difference was observed after overexpression of p.W197R and E32V. However, Bathon and Colls demonstrated that *PRKACA* mutations not only increase global PKA activity but also favor phosphorylation of specific substrates, such as histone 1 (H1), both *in vitro* and *in vivo*. Indeed, a 12- and 9-fold elevation of H1.4 phosphorylation is observed after overexpression of the p.L205R mutant in HEK293 and in CPA carrying the p.L206R mutation compared with nonmutated CPA, respectively.[39] Altogether, these results suggest that PKA activation due to *PRKACA* mutations could explain cortisol hypersecretion, whereas stimulation of cell proliferation could be linked at least partially to the hyperphosphorylation of new substrates like H1.4. Further studies are required to better characterize the molecular consequences of these mutations.

The genetic alterations affecting genes encoding the catalytic subunit of the PKA are not limited to *PRKACA,* as one mutation has recently been described in *PRKACB,* which encodes the catalytic subunit β of PKA, in a CPA of a patient with severe CS.[40] The missense variant, p.S54L, increases the sensitivity of the tetramer to cAMP and therefore leads to an elevation of PKA activity under basal conditions.[40] Although this is a rare genetic event identified in CPA, it highlights that genetic alterations affecting members of the PKA holoenzyme and favoring PKA activation play an important role in the development of cortisol-producing adrenocortical lesions.

Next-generation whole-exome sequencing was performed on CPAs not mutated at the *PRKACA* hots pot in order to identify others genetic alterations responsible for CPA.[41] This study resulted in the identification of genetic alterations both in known and new genes.[41] Indeed, as previously reported,[42] activating mutations have been identified in the *GNAS* gene encoding subunit α of the G protein. These mutations inactivate GTPase activity and therefore constitutively activate PKA signaling indirectly through activation of the adenylate cyclase.[41] Consistent with the causal role of eight somatic *GNAS* mutations identified in 74 CPAs, adrenal CS has been reported in 7.1% of patients with McCune–Albright syndrome due to postzygotic *GNAS* genetic defects.[29]

Somatic activating mutations in the *CTNNB1* gene encoding β-catenin are the most frequent genetic alteration identified after *PRKACA* mutations in CPA. In contrast to the other genetic alterations described above, constitutive activation of β-catenin does not cause PKA activation, but rather constitutive activation of the Wnt/β-catenin canonical pathway. β-catenin is degraded in the absence of Wnt ligands but accumulates in the cytoplasm and the nucleus of activated cells (Fig. 97.1). This activation, which is essential for normal adrenocortical development and differentiation, is tightly regulated, because abnormal β-catenin activation due, for instance, to *CTNNB1* missense mutations is sufficient to induce adrenocortical tumorigenesis.[43] Indeed, constitutive β-catenin activation characterized by nucleocytoplasmic β-catenin staining is the most frequent molecular alteration identified in both ACA and ACC.[43] Interestingly, the observation of constitutive β-catenin activation in nonsecreting and aldosterone-secreting ACTs indicates important variability in patient phenotypes that may be mediated by unique mutations or additional modifier genes.[43] In addition to *CTNNB1* activating mutations, alterations affecting others regulatory members of this pathway, particularly inactivating mutations of *APC* or *ZNRF3* have been identified in ACTs.[44] It can be hypothesized that the patients' phenotype and the form of the adrenocortical lesions rely on the genetic cause(s) as well as on the β-catenin dosage resulting from this alteration.

Animal Models

Animal models are essential assets for understanding physiology and physiopathology. Indeed, their characterization provides essential clues regarding the signaling pathways and molecular mechanisms responsible, for instance, for tumor growth and glucocorticoid hypersecretion in CS that cannot always be explored *in vitro*. Although a broad range of studies can be performed using animal models, this part of the chapter will focus on studies aiming to 1) elucidate the molecular causes of spontaneous CS development in certain species; 2) phenotype transgenic models carrying genetic alterations identified in CS patients.

Animal Models with Spontaneous Adrenocortical Tumors. Both ferrets and mice develop spontaneous adrenocortical lesions after gonadectomy. In both cases, it is thought that the chronic elevation of LH due to gonadectomy plays an important role in the adrenocortical tumorigenesis. Moreover, molecular studies revealed ectopic expression of LH receptor and CYP17, which are not robustly expressed in the adrenal (and are primarily gonadal proteins) in adrenocortical lesions.[45] This is associated with a switch from expression of the transcription factor *Gata4* to expression of *Gata6,* which normally regulates gonadal-specific gene expression and cell proliferation. Consistent with the gonadal-like cell phenotype identified in these adrenocortical lesions, the vast majority of these tumors in ferrets secrete sex steroids rather than glucocorticoid, even though a case of LH-dependent CS has been reported. Similar ACTs have been observed in other gonadectomized animals, including guinea pigs, hamsters, goats, and cats. Although sequencing of the ferret genome and identification of additional single nucleotide polymorphisms (SNPs) in mice and other model species would facilitate the characterization of genes influencing gonadectomy-induced adrenocortical tumorigenesis, studies have already identified genetic alterations associated with these tumors. For instance, linkage analysis in nonsusceptible (C57BL/6J) and susceptible (DBA/2J) mice already identified a major locus on chromosome 8 including, among others, *Sfrp1*, which encodes a negative regulator of Wnt/β-catenin, as a potential genetic factor for susceptibility. Moreover, the p.A172S substitution in steroidegenic factor 1 (*Sf1*) has been observed in a mouse strain with high tumor susceptibility and modified adrenocortical cell steroidogenic ability. Therefore, based on the role of Sf1 dosage in tumor growth in both human ACC and transgenic mouse models, it can be hypothesized that this polymorphism could lead to an increase in Sf1 expression and therefore promote ACT growth.[45]

CPAs are frequent in dogs, with one to two new cases per 1000 dogs reported per year. They are mostly unilateral, with only approximately 10% being bilateral lesions. In contrast to mice and ferrets, gonadectomy does not modify the incidence of CPAs in dogs; instead, they occur mainly in middle and old age, without sex predilection. As in humans, the diagnosis of adrenal CS is based on the determination of elevated circulating or urinary cortisol concentrations, which is not suppressed in response to a high dose of dexamethasone but is suppressed with suppressed circulating ACTH concentration.[45] Adrenalectomy is the best therapeutic option, but if the tumor is inoperable mitotane remains an option to target ACTs and metastases. A competitive inhibitor of 3β-hydroxysteroid dehydrogenase, trilostane, is used to control the clinical signs of glucocorticoid excess. The canine genome and SNP map, which are now publicly available, along with

SNP array technology could facilitate the use of spontaneous canine ACTs as a model to study adrenocortical tumorigenesis and to test potential treatment of these tumors that share a high degree of similarity with human ACTs.[45]

Xenografted and Genetically Modified Mouse Models. In recent decades, the identification of genetic alterations responsible for the development of ACT using omics approaches has been combined with transgenic techniques in mice to obtain crucial understanding of the molecular mechanism involved in adrenocortical tumorigenesis and hormonal secretion. To date, both xenografted and transgenic mice have been used to investigate the involvement of specific pathways. Although many models did not fully reproduce the human disorders, they provided important clues, such as highlighting the essential role played by PKA and the Wnt/β-catenin pathway, not only in adrenocortical tumorigenesis but also during adrenal cortex development and differentiation. This section provides a brief overview of the main findings made through the characterization of mouse models developed to study PKA signaling. More comprehensive reviews of mouse models developed to study adrenocortical function are already available.[46,47]

Consistent with the frequent genetic alterations affecting PKA regulators discovered in human CPAs, a number of mouse models presenting cAMP/PKA defects develop adrenocortical hyperplasia and cortisol hypersecretion. For instance, *Prkar1a* knockout is lethal in mice at embryonic day 9.5, and adrenocortical lineage-specific knockout has also been investigated. Interestingly, these mice develop a PPNAD-like phenotype characterized by a glucocorticoid hypersecretion associated with ACTH suppression and adrenocortical hyperplasia.[48] In accordance with the negative regulatory function of RIα on PKA activity, the endocrine hyperactivity is due to an abnormal activation of PKA signaling. This study therefore confirms that *PRKAR1A* loss is sufficient to induce adrenocortical hyperplasia and glucocorticoid hypersecretion through PKA activation. Furthermore, this phenotype is observed in females, first demonstrating that PKA effects are influenced by sex, which is consistent with the sexual dimorphism observed in most human adrenocortical disorders. Different approaches have been used in mouse models to elucidate the causes of this sexual dimorphism.[49,50] It appears that adrenal cortex renewal is faster in females than in males, partly because of dihydrotestosterone secretion in males. These studies illustrate the essential advances made in the comprehension of adrenocortical physiopathology through the characterization of animal models.

Altogether, the studies performed in the various models discussed herein and beyond have provided new knowledge and complementary information that can be translated to human disease. Moreover, in addition to the crucial molecular knowledge acquired through their characterization, these models can also be used for preclinical trials in order to test potential new, more targeted treatments for CS, which are needed to improve patients' conditions.

DIAGNOSIS

KEY POINTS

- Before evaluating for possible Cushing syndrome (CS), it is essential to obtain a careful history, excluding exogenous glucocorticoid intake.
- The diagnosis of CS depends on at least two different first-line tests (urinary free cortisol, midnight salivary cortisol, and cortisol after low doses of dexamethasone suppression test).
- The diagnosis of CS involves three steps: suspicion based on signs and symptoms, documentation of the presence of hypercortisolism, and determination of its cause.

Clinical Manifestations

CS is the prototypical metabolic syndrome. It is important to emphasize that, in severe hypercortisolism, catabolic changes are most useful for making the differential diagnosis. The major discriminative symptoms and signs of CS in adults include the following: thinning of the skin, facial plethora, proximal muscle weakness, extremity wasting with increased fat in the abdomen and face, wide purplish striae, and bruising with no apparent trauma (Fig. 97.2).[27] In children/adolescents, there is a retardation of growth velocity or cessation of growth and arrest of pubertal development associated with remarkable obesity (Table 97.2).[51] The less discriminative symptoms and signs comprise: global obesity, supraclavicular fat pads, infertility, hypogonadotropic hypogonadism, diabetes, dyslipidemia, hypertension, osteopenia, obstructive sleep apnea, and more (Table 97.3).

An essential clue to the presence of glucocorticoid excess is the simultaneous development and increasing severity of several of these symptoms. Nevertheless, many of these signs and symptoms can occur in individuals without hypercortisolism, and not all patients with CS present with obvious features.[51]

Clinical manifestations of CS are classified according to the involvement of the different systems: cardiovascular, reproductive, musculoskeletal, dermatologic, and neuropsychiatric. In addition, hypercortisolism is associated with a higher susceptibility to infections and to an immunosuppressive state.[52]

The presence and relative severity of symptoms vary, as well as the degree and duration of hypercortisolism and the presence or absence of androgen excess (because hypercortisolism alone causes neither hirsutism nor pustular acne). Androgen excess occurs only in women with ACC or ACTH-stimulated hyperandrogenism (the adrenal gland being a major source of androgen production in women but not men). ACA causing adrenal Cushing generally secretes only glucocorticoids.[53]

In patients with ACAs, both the degree of hypercortisolemia and many of the clinical manifestations of CS tend to be less severe in patients greater than 50 years of age.[53] Many patients with incidentally discovered ACAs have mild autonomous cortisol excess (MACE) without specific signals and symptoms of CS; however, glucose intolerance, obesity, and hypertension are common.[54]

Menstrual irregularities are common in women with CS. The menstrual abnormalities correlate with increased serum cortisol and decreased serum estradiol concentrations, but not with serum androgen concentrations. Because both LH and follicle-stimulating hormone levels are low, the menstrual irregularities appear to be due to the suppression of the secretion of gonadotropin-releasing hormone by high levels of cortisol.[55]

Women with some types of CS have signs of androgen excess (most commonly ACC). Signs of androgen excess in CS are most common in women with adrenal carcinomas. These tumors often secrete large amounts of androgenic precursors, because they are inefficient at converting cholesterol to cortisol. Androgen excess in affected women can cause hirsutism, oily facial skin and acne on the face, neck, or shoulders, and increased libido.[55] ACC causes virilization, including temporal balding, voice deepening, and clitoral hypertrophy. Prepubertal males/females may develop precocious isosexual or heterosexual puberty, respectively.[56]

Hypertension, low bone mineral density, and pathologic fractures (ribs, feet, and vertebrae are frequently affected sites) are common, and osteopenia in young patients with CS should raise the index of suspicion of PPNAD. More rarely, adenomas may also secrete various steroids (e.g., cortisol and aldosterone), androgens, or estrogens, but this should raise the suspicion of a malignant tumor.[5]

Hormonal Evaluation

The diagnosis of CS involves three steps: suspicion based on signs and symptoms, documentation of the presence of hypercortisolism, and

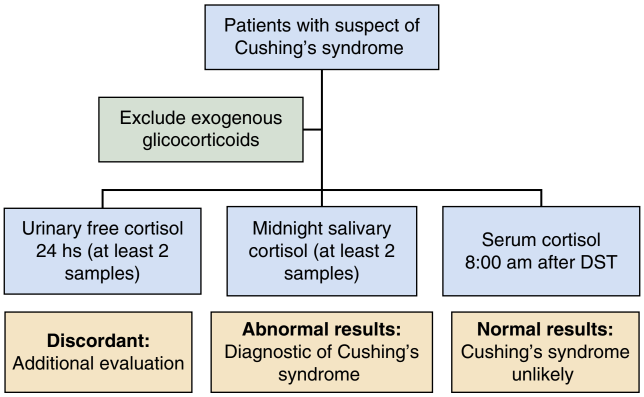
SIGNS AND SYMPTOMS	
More Discriminative	**Percentage (%)**
Facial plethora	90
Easy bruising	65
Proximal myopathy/weakness	60
Unusual osteopenia or osteoporosis/fracture for age	50
Skin finding*	75
Decreasing growth velocity	70–80
Striae (especially if red or purple and more than 1 cm wide)	70–90

*Skin atrophy, acne, plethora, hypertrichosis, hirsutism, acanthosis nigricans, hyperpigmentation, alopecia, purpura, and many other dermatological conditions.

TABLE 97.3 Less Discriminative Signs and Symptoms of Cushing Syndrome

SIGNS AND SYMPTOMS	
Less Discriminative	**Percentage (%)**
Weight gain or obesity/abdominal obesity	95
Facial fullness	90
Decreased libido/erectile dysfunction	90
Menstrual abnormalities/amenorrhea	80
Arterial hypertension	75
Hirsutism	75
Depression/emotional lability	70
Dyslipidemia	70
Impaired glucose tolerance/diabetes mellitus	60
Dorsocervical fat pad/supraclavicular fullness	50–70
Kidney stones	50
Exophthalmos	45
Polyuria	30
Headache	20–50
Back pain	20–50
Peripheral edema	20–50
Unusual infections/fungal infections	20–50
Hypokalemia	10–70
Acne	<20
Alopecia/female balding	<20
Hyperpigmentation	10

determination of its cause. The literature reports a variety of approaches and test combinations.[57] All tests are biochemical assessments of abnormalities of the hypothalamic–pituitary–adrenal axis. Before evaluating for possible CS, it is essential to obtain a careful history and to exclude exogenous glucocorticoid intake. The initial diagnostic tests for hypercortisolism should be extremely sensitive, even though the diagnosis may be excluded later by more specific tests.[57] The diagnosis of CS depends on at least two different first-line tests being unequivocally abnormal, as described in Fig. 97.3.[57] These include abnormal overnight dexamethasone suppression test with 1 mg (morning cortisol cutoffs <1.8 ug/dL or 50 nmol/L), at least two samples of low or suppressed ACTH, loss of circadian rhythm (increased serum or salivary midnight cortisol levels), and increased urinary free 24-hour cortisol.[58,59] The 1-mg dexamethasone suppression test is considered to be very sensitive for adrenal Cushing. However, when it is the only alteration, and the cortisol level is between 50 and 138 nmol/L, the patient can be considered as having possible autonomous cortisol excess. It is then advised to repeat the test few months later. If the test is still abnormal, and a third investigation remains abnormal, the diagnosis of MACE can be made. Some rare patients have cyclic CS, characterized by excess cortisol episodes alternating with periods of normal cortisol secretion. Hypercortisolism episodes can occur regularly or irregularly, with intercyclic phases ranging from days to months.[57] For patients with suspected cyclic CS, it has been suggested that urinary free cortisol (UFC) or late-night salivary cortisol can facilitate making the diagnosis better than the dexamethasone suppression text. If initial testing is normal, but clinical suspicion is high, follow-up with repeated testing is suggested. True cyclic CS is relatively rare, however, and variability in UFC excretion is common to all forms of CS.[58]



Patients with suspect of Cushing's syndrome
Exclude exogenous glicocorticoids
Urinary free cortisol 24 hs (at least 2 samples)
Midnight salivary cortisol (at least 2 samples)
Serum cortisol 8:00 am after DST
Discordant: Additional evaluation
Abnormal results: Diagnostic of Cushing's syndrome
Normal results: Cushing's syndrome unlikely

Figure 97.3 The Endocrine Society's Clinical Practice Guidelines recommend screening for Cushing syndrome using tests with high accuracy to evaluate hypothalamic-pituitary-adrenal axis integrity: 1) Excess total endogenous cortisol secretion, based on measuring 24-h urinary free cortisol levels; 2) loss of the circadian rhythm of cortisol secretion, based on midnight or late night salivary cortisol levels; 3) loss of normal cortisol feedback, assessed with the low-dose (1-mg) dexamethasone suppression test to identify autonomous cortisol secretion.

Once the diagnosis of CS is established, additional evaluation is done to identify the cause of the hypercortisolism. Measurement of plasma ACTH is therefore critical to differentiating ACTH-dependent from ACTH-independent CS. ACTH is secreted in a pulsatile fashion, dictating the same circadian rhythm to cortisol, and is extremely sensitive to stress. Its half-life in plasma is short due to plasmapeptidase activity. For these reasons, clinicians should collect several blood samples in tubes containing enzymes inhibitors (preferably two or three samples over 30 minutes) and maintain the samples at low temperatures before separation into aliquots.[60] Plasma ACTH concentrations are low in most patients with adrenal CS; however, up to 25% may present values within the normal range. It remains uncertain whether assay methodology contributes to this unexpectedly normal lab value, or whether there is incomplete suppression of pituitary ACTH secretion.[58,59] ACTH concentrations have rarely been frankly nonsuppressed in cortisol-secreting ACC due to the ectopic production and autocrine action of ACTH by the ACC.[51] In addition to patients with adrenal CS presenting measurable or normal ACTH concentrations, 10% of patients with Cushing disease display ACTH values below 10 pg/mL (2 pmol/L), thereby blurring the boundaries between the etiologies. To correctly diagnose patients falling into this gray area, stimulation with corticotropin-releasing hormone can prove useful; patients with pituitary-dependent hypercortisolism will mount an ACTH response to the stimulus, whereas patients with ACTH-independent hypercortisolism will not.[51]

Recently, adrenal steroids other than cortisol have been used for diagnosis of subclinical hypercortisolism, as measured by liquid chromatography-tandem mass spectrometry (LC-MS/MS). This has been further supported by an LC-MS/MS steroid profiling study establishing a panel of steroids that can be used to identify patients with CS and discriminate between those with and without ACTH-dependent subtypes.[27] Other studies have indicated that urinary steroid profiling

may be useful for differential diagnosis of benign versus malignant ACTs.[61,62] These methods are predicted to improve both diagnostic accuracy and tumoral surveillance of adrenal tumors.

ETIOLOGY

KEY POINTS

- Adrenal Cushing can be caused by bilateral or unilateral neoplasia (hyperplasias or tumors).
- Bilateral tumors are more often associated with genetic origin.
- The evaluation includes clinical, hormonal, and radiological imaging and possible genetic investigation.
- Adrenocortical adenomas is frequent in the general population, frequently diagnosed in patients with adrenal incidentaloma, and much more often responsible for mild autonomous cortisol excess (MACE) than overt Cushing.
- Adrenocortical carcinoma is a rare tumor with a poor prognosis.
- Primary bilateral macronodular adrenal hyperplasia is a rare adrenal cause of overt Cushing but is more frequently responsible for MACE.
- Primary pigmented nodular adrenocortical disease is responsible for overt Cushing and is most often associated with Carney complex.

Adrenal Cushing can be caused by bilateral or unilateral tumors (Fig. 97.4). Unilateral tumors are more frequent than bilateral tumors, and are usually sporadic in adults. In contrast, bilateral tumors are more often of genetic origin. Unilateral tumors can be benign (ACA) or malignant (ACC). ACAs are common in the general population, diagnosed incidentally, do not often secrete excessive cortisol and hence do not frequently result in over Cushing syndrome.[63,64] ACCs are rare tumors with a poor prognosis. Bilateral tumors can be divided in two groups, with clearly different pathology: micronodular adrenal hyperplasia and PMAH. These two entities are clearly different from the pathophysiological, as well as the morphological and clinical, points of view (Fig. 97.4). Clinical and hormonal investigations associated with imaging, and in some specific situations genetic analysis, can in most cases diagnose the cause of adrenal Cushing. However, in operated patients the pathology finding is fundamental, especially for the diagnosis of malignant tumors.

Unilateral Tumors

The clinical, hormonal, and imaging presentation of ACA can differ from those of ACC. However, when the ACC is localized to the adrenal gland (European Network for the Study of Adrenal Tumors [ENSAT] stage 1 or 2), the differential diagnosis can be difficult, and a careful pathological examination is fundamental. The histological diagnosis between a benign and a malignant adult ACT is based on the Weiss score system, and a malignant ACT must meet at least three out of nine criteria.[65,66]

Adrenocortical Adenoma

Cortisol-secreting adrenal adenoma is diagnosed by the investigation of clinical signs of CS or by the investigation of adrenal incidentaloma. In the latter, cortisol autonomous secretion can be mild or even undetectable by routine hormonal investigations in patients with no specific signs of CS. From the clinical perspective these two situations are clearly different and will be presented separately. At pathological investigation, cortisol-producing adenomas are enriched in zona fasciculata-like clear cells with variable amounts of compact cells or pigment deposition. The presence of cortical atrophy in the adjacent adrenal cortex in the case of cortisol excess reflects the decreased levels of circulating ACTH, which has a trophic effect required for maintenance of the adrenal cortex. The Weiss score of an ACA is most often 0 or 1, and less frequently 2.

ACAs responsible for overt CS are usually diagnosed between the age of 35 to 50 years, and more frequently in women.[67] They represent the most frequent adrenal cause of CS. A benign adrenal cortisol secreting tumor typically oversecretes cortisol but no androgens nor mineralocorticoids, in contrast to malignant adrenal tumors. The clinical signs are therefore due to cortisol excess with facial-truncal obesity, hypertension, and diabetes, as well as catabolic signs (muscle weakness, osteoporosis), often starting 2 to 4 years before diagnosis.

In ACA responsible for overt CS, the UFC, as well as midnight salivary or plasma cortisol, is increased. Plasma cortisol is clearly elevated after the 1-mg dexamethasone test, and ACTH levels are usually completely suppressed. Levels of the adrenal androgen dehydroepiandrosterone (DHEA) are low due to the lack of ACTH stimulation. On imaging, these adenomas can have typical characteristics of benign lipid-rich tumors on computed tomography (CT) scan or magnetic resonance imaging (MRI) (Fig. 97.5). However, spontaneous density on CT scan is less often low than in benign adrenal incidentalomas, probably reflecting the increased steroid synthesis of these adenomas.[68] ^{131}I-iodocholesterol (NP-59) scintigraphy typically shows a unilateral uptake of the tracer, with the normal contralateral adrenal being inactive when the circulating ACTH is suppressed.

These days, most ACAs are diagnosed by investigation of an adrenal incidentaloma. In this situation, specific clinical signs of cortisol excess are absent, in contrast to patients with ACA causing overt Cushing. However, diabetes, obesity, or hypertension is present in 30% to 70% of cases, and the potential role of autonomous cortisol secretion in these comorbidities should be discussed in this setting for patient management. In these incidentally found ACAs, the first diagnostic step is imaging. It is crucial to demonstrate whether a new adrenal mass is benign or malignant. Typically, CT scan shows a homogenous mass smaller than 4 cm and with a low spontaneous density (<10 Hounsfield units [HU]) due to the rich lipid content of the tumor, defining the mass as a benign lipid-rich ACA. The chemical shift observed on MRI reflects the same characteristics. When the spontaneous density on CT scan is not low, determination of washout after media contrast injection is important. A relative washout of greater than 40% and an absolute washout of greater than 60% suggests a benign ACA. Autonomous cortisol secretion in a patient with a fortuitously discovered ACA will be screened for by a systematic 1-mg overnight test of dexamethasone suppression of serum cortisol. A postdexamethasone cortisol level of less than or equal to 50 nmol/L (1.8 ug/dL) excludes cortisol dysregulation. It has been accepted that a postdexamethasone serum cortisol level between 51 and 138 nmol/L suggests possible autonomous cortisol secretion, and a postdexamethasone cortisol level greater than 138 nmol/L is evidence of autonomous cortisol secretion (Fig 97.6). In this situation, further hormonal investigations with UFC, midnight salivary cortisol level assay, and ACTH level assay will be done to better assess cortisol excess. In most cases of possible autonomous cortisol secretion (i.e., serum cortisol levels after 1-mg overnight dexamethasone of between 51 and 138 nmol/L), additional hormonal investigations will be normal or show only mild alterations. In cases of mild cortisol alterations, careful analysis of patients' comorbidities is important to guide management. These comorbidities can include hypertension, glucose intolerance or diabetes mellitus, obesity, osteoporosis, dyslipidemia, and psychological patterns.

Adrenocortical Cancer

ACC can be diagnosed by the investigation of endocrine signs of steroid excess or after investigations of an adrenal incidentaloma, and less frequently based on symptoms due to tumor mass or metastasis. Most tumors demonstrate steroid oversecretion, often of both glucocorticoids and androgens.[69] ACC represents on an average 1% of adrenal

Management of adrenal incidentalomas: European Society of Endocrinology Clinical Practice Guideline in collaboration with the European Network for the Study of Adrenal Tumors. *Eur J Endocrinol*. 2016;175:G1–G34.)

incidentalomas in surgical series.[63] Careful investigation of adrenal incidentalomas with rigorous imaging and stringent criteria is important, as this could help diagnose ACC at an earlier stage. Pathologically, ACCs are usually large tumors with nests intermingled with solid and trabecular areas circumscribed by a fibrous capsule.[66] Cells are usually eosinophilic or vacuolated. Immunostaining for SF1 or melan A can be used to determine the adrenocortical nature of the tumor, along with pathology analysis (both macroscopic and microscopic), and this is especially important to avoid misdiagnosing a nonsecreting tumor. Cytopathological alterations are analyzed and quantitated to determine the Weiss score. When the score is above 3, the adrenal tumor is classified as an ACC. A Weiss score of 3 is a suspicious tumor.[65] Despite an overall low 5-year survival rate (below 30% in most series), some tumors will not show recurrence after surgical removal, and others will have a relatively slow metastatic progression. Prognostication of ACC is not easy, but Ki-67 has demonstrated some prognostic value.[70] Genomic analysis has identified subgroups of ACC with different outcomes, and molecular markers have been suggested.[71,72] Among the various clinical parameters that have been shown to impact ACC prognosis, tumor staging has been demonstrated as one of the most important. The ENSAT staging system is the most commonly used system and relies on surgical findings and extended workup. Four different stages are differentiated with this score.[73] Stage 1 and stage 2 tumors are localized to the adrenal cortex and present a maximum diameter below or above 5 cm, respectively. Locally invasive tumors or tumors with regional lymph node metastases are classified as stage 3, whereas stage 4 consists of tumors with distant metastases. The prognosis of stage 1 and 2 tumors is better than that of stage 3 or 4 tumors. When careful hormonal investigations are performed, it appears that the majority of ACCs are secreting tumors. In contrast to benign ACTs (which usually secrete a single class of steroid), ACCs can secrete various types of steroids.[62] Cosecretion of androgens and cortisol is the most frequent case and is highly suggestive of a malignant ACT. In ACC, cortisol oversecretion will induce the same symptoms as in ACA. By contrast, androgen oversecretion, which is a main feature of steroid excess in ACC, may induce various manifestations in women: hirsutism, menstrual abnormalities, infertility, and eventually frank virilization (alopecia, deepening of the voice, clitoral hypertrophy). ACC can also secrete mineralocorticoids and steroid precursors, leading to hypertension, edema, or hypokalemia. Estrogen oversecretion can be observed in rare cases. Estrogen excess is responsible for gynecomastia in males. Routine hormonal investigations therefore aim to characterize the steroid secretory profile of ACC. Diagnosis of steroid excess is useful to establish the adrenocortical origin of the tumor and can be used for follow-up. ACTH-independent cortisol oversecretion will be screened for as described for ACA. Furthermore, hormonal workup will include plasma 17-OH progesterone, the adrenal androgen DHEA, plasma testosterone in females, and estradiol in males. Other steroids including compound S, DOC, delta 4 androstenedione, and estradiol can be overproduced by the tumor. Secretion of aldosterone by ACC is not frequent and can be detected by plasma aldosterone and renin assays.

Radiological imaging is an essential diagnostic step for ACC, especially in cases of incidentaloma. It is important both for the diagnosis of malignancy of an adrenal mass, but also for the extended workup.[73] CT scan shows a unilateral mass that is most often large (greater than 5–6 cm, typically 10 cm or more), lowering the kidney (Fig. 97.5). Apart from the size of the tumor, the features suggestive of malignancy are the lack of homogeneity, with foci of necrosis and irregular margins and a high spontaneous density observed before contrast media injection during CT scan (above 10 HU), indicating a low-fat content, in contrast to what is often found in ACA. When the spontaneous density is above 10 HU, dynamic measurement of contrast-enhanced densities may provide additional information to help distinguish between benign and malignant lesions. The washout after contrast media injection during CT scan is typically below 50% in ACC. CT scan can also help detect local invasion and distant metastases (liver, lung). positron emission tomography (PET) scan with (^{18}F)-fluorodeoxyglucose (FDG) shows high uptake of the tracer in the primary tumor as well as metastasis, and can be informative for both the diagnosis of malignancy and for extended workup.[74]

Bilateral Adrenocortical Tumors

Bilateral ACTs consist of multiple benign nodules observed in both adrenals, with various patterns of internodular adrenocortical tissues. They are often considered to be a form of nodular adrenal hyperplasia. However, from the molecular point of view, activation of specific oncogenic pathways independently in each adrenal nodule has been demonstrated in some cases, and from the mechanistic point of view, the term hyperplasia is somewhat misleading. The bilateral nature is easily explained in cases for which a hereditary genetic defect has been demonstrated.[75]

Bilateral ACTs can be divided in two groups, with clearly different pathology: micronodular adrenal hyperplasia and PMAH.[18,66] The most classic and frequent form of micronodular adrenal hyperplasia is PPNAD. In micronodular adrenal hyperplasia, multiple small nodules less than 10 mm are observed. In macronodular adrenal hyperplasia, by contrast, some large nodules above 1 cm are observed. PMAH is also referred to as PBMAH and was previously called ACTH-independent macronodular adrenal hyperplasia. The latter term is not used anymore, since the demonstration of the role of locally produced ACTH on cortisol dysregulation.

Micronodular Adrenal Hyperplasia and Primary Pigmented Nodular Adrenal Disease

Micronodular adrenal hyperplasias are multiple small micronodules that are disseminated in both adrenals and are responsible for adrenal Cushing. In very young children with overt Cushing some rare cases of non-pigmented nodules have been reported.[76] However, most patients with micronodular adrenal hyperplasia present with PPNAD.[77] This is a rare cause of ACTH-independent hypercortisolism, most often diagnosed in children and young adults. Its name comes from the particular macroscopic aspect of the adrenals, with pigmented micronodules widespread in the cortex of both adrenals. Adrenal glands from patients with PPNAD are usually normal in size, and their weight is normal or moderately increased (4–15 g). PPNAD pathological characteristics are quite unique already from macroscopic examination: the adrenal cortex is dotted with numerous small pigmented nodules. The multiple pigmented micronodules are usually quite small (0.1–0.3 mm), but some can be slightly larger, although they are rarely larger than 1 cm. Some rare unique pigmented macronodules with a somatic β-catenin mutation have been reported. The adjacent adrenocortical tissue is in most cases atrophic. PPNAD is most often observed in patients with CNC, a familial form of multiple neoplasia predisposition syndrome, responsible for several types of tumor, including other endocrine lesions: somatotroph pituitary adenomas, testicular Sertoli cell calcified tumors, and benign or malignant thyroid lesions, but also nonendocrine manifestations, mainly cardiac myxomas, pigmented skin lesions (lentiginosis and naevi), and melanocytic schwannomas.[78,79] CNC is inherited in an autosomal dominant manner. Inactivating germline mutations of the *PRKAR1A* gene, coding for the regulatory subunit R1A of PKA, located at 17q22-24, are found nowadays in more than 80% of the patients with a classic form of the disease. Interestingly, germline *PRKAR1A* mutation can be found in half of patients with PPNAD as the only manifestation of CNC. The prevalence of PPNAD in patients with CNC is approximately 60% and is the most common endocrine feature seen in this disease.[80] PPNAD is more frequent in females (approximately 70% of patients), with a median age at diagnosis of 34 years. It is rare but possible before the age of 4 years, and it is rarely diagnosed after the age of 45 years, even during systematic screening of patients with known CNC. In autopsy series of CNC patients, histological evidence of PPNAD was present in almost all patients.[78] Diagnosis of CS in PPNAD is often difficult, because hypercortisolism can develop progressively over years. In contrast, in some patients a rapid, significant burst of cortisol excess can be observed that may spontaneously regress. Indeed, in some cases of PPNAD clearly cyclic hypercortisolism has been observed. CS due to PPNAD occurring during pregnancy has also been observed. PPNAD can now also be diagnosed by systematic screening in patients with CNC, who are investigated for other clinical manifestations of the complex or after familial screening. The mean time between appearance of the first symptoms and diagnosis was approximately 4 years in historical series. Despite the unusual time course of CS that can be observed in some patients with PPNAD, clinical signs are quite similar to the observations made in patients presenting with other causes of hypercortisolism. Due to the occurrence of CS in children, short stature was observed in 29% of the 72 patients reported by Carney.[81] However, pediatricians should be aware that growth arrest is not a constant finding in children with PPNAD. This could be explained in some cases by cyclic hypercortisolism. It could be postulated that simultaneous growth hormone dysregulation due to somatotroph hyperplasia or adenoma in patients with CNC may also protect at least partly from the consequences of cortisol excess on growth. Osteoporosis is also frequently observed and can constitute a long-term consequence of CS, especially in patients in whom the diagnosis of PPNAD was delayed. Urinary cortisol is increased in most patients at the time of diagnosis of PPNAD, but its level can be highly variable. The circadian rhythm of cortisol is completely abolished. As for others causes of ACTH-independent CS, plasma levels of ACTH are suppressed in patients with PPNAD. Dexamethasone fails to suppress cortisol, even with administration of high doses. Interestingly, a paradoxical rise in urinary cortisol can be observed after dexamethasone treatment, particularly with administration of high doses (8 mg/day).[82] This could be helpful for the diagnosis of PPNAD, especially in patients with normal basal urinary cortisol levels.[83] An increase in urinary cortisol of at least 100% seems quite specific to PPNAD. This stimulatory effect of glucocorticoid can be observed during primary culture of PPNAD tissues *in vitro*. On CT scan, adrenals can appear normal or moderately enlarged (Fig. 97.5), but higher definition (CT slice thickness <5 mm) allows visualization of small, round, hypodense nodules, usually less than 10 mm. However, adrenal macronodules associated with micronodules can be observed in a subset of rare adult patients.[84] Adrenal NP-59 scintigraphy shows bilateral uptake that can be asymmetric in patients with the presence of unilateral macronodule.

Primary Macronodular Adrenal Hyperplasia

PMAH is typically characterized by the presence of several bilateral adrenal macronodules (diameter >10 mm). PMAH has long been called AIMAH, but the discovery of intraadrenal ACTH synthesis responsible for local stimulation of cortisol production prompted a change of the terminology to PBMAH.[85] Because PMAH more rarely can be also asymmetric, and in some rare cases apparently unilateral, the term PMAH is also used by extension to include the apparently unilateral cases, but this is clearly the same disease group. The ectopic ACTH is secreted by PMAH adrenocortical cells localized in the subcapsular region and in hyperplasic nodules. These cells express proconvertase 1, the cleavage enzyme needed to process the ACTH-precursor proopiomelanocortin to mature ACTH. The regulation of this “ectopic” ACTH differs from the regulation of pituitary ACTH secretion.[86] In operated PMAH, macroscopically, the adrenal glands are classically enlarged, harboring multiple yellowish nonpigmented nodules larger than 1 cm. When patients are operated for overt Cushing syndrome, the adrenal weight is usually between 45 to 100 g, equivalent to 10- to 25-fold the normal adrenal weight. Internodular atrophy is typically observed but not constant, and in some cases hyperplasia of the internodular cortex can be observed, which may then not be a diagnostic criterion. This suggests heterogeneity of this disease that is also illustrated by the various genetic origins. Adrenal nodules are usually composed of two cell types, without mitosis: clear cells with large cytoplasm also known as spongiocytes, with 3β-hydroxysteroid dehydrogenase expression, and compact cells with 17-hydroxylase expression. There is no unifying histopathologic feature to distinguish PMAH from other benign adrenal nodules.

Interestingly, in PMAH cortisol secretion dysregulation is almost always associated with illegitimate membrane receptor expression.[87] This abnormal regulation of cortisol was first investigated in detail in PMAH and later appeared to also be possible in some ACAs. In this situation, cortisol secretion is stimulated by a ligand that physiologically does not control cortisol. Various stimulating ligands binding to protein GPCRs have been described, including glucose-dependent insulinotropic peptide (GIP), which is responsible for food-dependent CS, LH/hCG, which is responsible for CS during pregnancy and after menopause, vasopressin, catecholamines, and serotonin 5-HT. Most of these illegitimate GPCRs stimulate adenylyl cyclase. From a clinical point of view, the rhythm of cortisol secretion can be modified by these illegitimate receptors. For instance, in food-dependent CS, fasting plasma cortisol will be low, while postprandial cortisol will be increased. The upright position may lead to plasma cortisol stimulation in patients with illegitimate adrenergic or vasopressin receptor expression.

PMAH is typically diagnosed in patients between 40 and 65 years of age.[88] As for ACA, PMAH is nowadays diagnosed after investigations of clinical signs of cortisol excess or in patients with bilateral adrenal incidentalomas.[89] PMAH is slightly more prevalent in women. The degree of cortisol autonomous secretion is extremely variable as in ACA, and overall there is a tendency for a positive correlation between adrenal nodule size and cortisol dysregulation. When PMAH is diagnosed in patients with adrenal incidentaloma, cortisol dysregulation is usually mild or absent, and the adrenal volume is moderately increased. It should be noted that 5% to 15% of adrenal incidentalomas are bilateral. In most cases, bilateral adrenal masses represent benign bilateral adrenocortical disease and can be bilateral adenomas or macronodular hyperplasia. As for unilateral incidentalomas, careful imaging analysis is important, and each side needs to be rigorously analyzed to confirm the benign characteristics of the nodules on both sides and that the patient do not present a different type of lesions on each side. In bilateral incidentalomas, if surgery is not performed, thereby allowing pathological diagnosis, it might be difficult in very moderate forms to differentiate PMAH from bilateral adenomas, although careful imaging analysis may help when multiples nodules are visible.

Significant cortisol excess in PMAH leads to frequent overt Cushing syndrome leading to weight gain with android obesity, proximal myopathy, buffalo neck, red stretch marks, skin fragility, and easy bruising, as well as hypertension, diabetes, venous thromboembolism, osteopenia, or osteoporosis, and the clinical picture can in some rare cases be severe. Hormonal investigations usually demonstrate marked alterations, with increased 24-hour UFC, midnight plasma or salivary cortisol, and morning plasma cortisol after 1-mg overnight dexamethasone suppression test, as well as suppressed ACTH. Patients diagnosed after investigation of bilateral adrenal incidentaloma do not present many specific signs of cortisol excess, but they frequently suffer from hypertension, diabetes, or obesity. Interestingly, some data suggest that there is 2.5-fold increase in the presence of vertebral fragility fractures in patients with bilateral adrenal incidentaloma than in those with unilateral adrenal adenoma, even after adjusting for the degree of cortisol hypersecretion and bone mineral density.[90] Hormonal investigations in these moderate forms frequently show an insufficient suppression of plasma cortisol during the 1-mg overnight dexamethasone suppression test. Interestingly, this alteration is also more frequent in bilateral than in unilateral adrenal incidentalomas.[91] Plasma ACTH in these moderate forms with possible autonomous cortisol secretion is usually low but not completely suppressed, and UFC is usually not elevated. In addition, in order to demonstrate the presence of aberrant GPCR expression, the cortisol response to different stimuli could be assessed, as described in Table 97.4. These investigations are interesting for research purposes, but could help in some selected cases to identify potential response to medical therapy.

In PMAH patients, CT scan shows enlarged adrenal glands with at least two nodules larger than 1 cm in diameter (Fig. 97.5). This is clearly different from PPNAD, in which adrenal glands typically appear either normal or moderately and diffusely enlarged. PBMAH nodules usually present similarly to unilateral benign lesions, with a low spontaneous density below 10 HU and rapid washout after intravenous iodine contrast injection. Similar to the observed variability in biochemical presentation, the morphological aspect of the adrenal glands is also highly variable, ranging from a single nodule on each adrenal gland to massively enlarged adrenals, up to 10 cm and larger, with numerous nodules. The internodular adrenal cortex can be hyperplastic or hypoplastic. According to different series, *ARMC5*-mutated index case patients have significantly larger adrenals and more numerous nodules than wild-type patients, correlated with the level of cortisol excess. Abdominal MRI also show characteristics of benign lipid-rich lesions. In case of noncharacteristic imaging features and malignancy suspicion, FDG-PET/CT is often used to assess unilateral adrenal masses. At present, it is difficult to know how to interpret FDG-PET/CT in PMAH, as high FDG uptake has been demonstrated in some cases of PMAH.[90] NP-59 scintigraphy can be useful in demonstrating bilateral autonomous activity in patients with low ACTH levels. It could also provide evidence for asymmetric glucocorticoid output, in which case unilateral adrenalectomy would be an option.

TABLE 97.4 Comorbidities to be Investigated in Patients with Mild Autonomous Cortisol Secretion

Hypertension
Glucose intolerance/diabetes mellitus
Obesity

Osteoporosis

MANAGEMENT OF ADRENAL CUSHING SYNDROME

KEY POINTS

- The surgical procedure used depends on the severity of the hypercortisolism and the malignancy potential.
- Deciding on the right approach for mild autonomous cortisol excess can be challenging, and each case should be individually evaluated based on the progression of metabolic syndrome.
- Steroidogenesis inhibitors can be used in patients with a severe condition as preparation before surgery or for nonoperable tumors.

Management will aim to correct cortisol excess regardless of the etiology, and, in the case of a malignant or suspicious tumor, to achieve tumor control. Management is discussed with a multidisciplinary team, and identifying the cause of adrenal Cushing is a major element in the therapeutic choice. Assessment of the level of autonomous cortisol secretion and its consequences is also a key element in this discussion. While there is no debate about the need to treat overt Cushing, there is more debate regarding benign lesions responsible for possible autonomous cortisol secretion and eventually mild adrenal Cushing. In this situation the treatment plan will be decided on an individual basis based mostly on analysis of the potential consequences of cortisol excess. Medical treatment will be based mostly on steroidogenesis inhibitors and specific treatment of the complications of cortisol excess. Surgery by a laparoscopic or conventional approach, depending on the causative tumor, is always discussed and in many patients can be the single treatment approach used. Also, both medical and surgical treatment can cause transient or definitive adrenal insufficiency that will need specific management.

Medical Treatment with Steroidogenesis Inhibitors (Table 97.5)

The medical approach to controlling steroid excess in adrenal Cushing is mostly discussed in patients with a severe condition as preparation

TABLE 97.5 Level of Action, Usual Dose, Advantages, and Side Effects of Oral Steroidogenesis Inhibitors

Drug	Level of Action	Daily Dose Range	Delay of Action	Side Effects and Potential Problems
Ketoconazole	Inhibits steroidogenic enzymes at multiple levels	200–1200 mg orally two to three times per day	Rapid	Rare hepatotoxicity requiring monitoring of liver enzymes (weekly during first month and monthly for the following 6 months); potential for drug–drug interactions
Metyrapone	Inhibits 11β- hydroxylase and aldosterone synthase	500–6000 mg orally three to four times per day	Rapid	Hirsutism, hypertension, hypokalemia, digestive intolerance
Osilodrostat	Inhibits 11β-hydroxylase and aldosterone synthase	1–30 mg orally two times per day	Rapid	Potential for hirsutism, hypertension, hypokalemia; potential for drug–drug interactions, QT interval monitoring (electrocardiogram)
Mitotane	Inhibits steroidogenic enzymes at multiple levels, cytotoxic and cytolytic effects on the adrenal cortex	0.5–9 g orally three times per day	Delayed (weeks/ months)	Digestive intolerance, increased cholesterol and liver enzyme, neurological intolerance (mostly in case of high blood mitotane levels) Teratogenic; Potential for drug–drug interactions

before surgery or for nonoperable tumors (especially metastatic ACC). It could be also discussed in patients with a mild form of the disease as an alternative to surgery or to determine the role of cortisol dysregulation in its potential complications, but at present there is almost no evidence base directing decision-making in this situation. The drug dose needed to control adrenal Cushing is often lower than that needed for Cushing disease, likely because increased ACTH resulting from lowered cortisol does not occur to the same extent as it does in pituitary Cushing. All steroidogenic inhibitors can cause, as a consequence of their efficacy, varying degrees of adrenal insufficiency. Regular monitoring of cortisol levels is important both for efficacy and safety assessment. For drugs like metyrapone or osilodrostat that increase 11-deoxycortisol, cortisol should be measured by tandem mass spectrometry to avoid the possible cross-reactivity between 11-deoxycortisol and cortisol in immunoassays. Patient should be educated to immediately start glucocorticoid substitution therapy when sign of adrenal insufficiency occur. In cases of demonstrated low cortisol levels suggestive of significant adrenal insufficiency, the drug dosage can be decreased, or a systematic glucocorticoid substitutive treatment utilized (“block and replace” scheme).

Ketoconazole. Ketoconazole was initially used as an antimycotic drug, but can also inhibit steroidogenesis. It acts on several steroidogenic enzymes, such as CYP11A1, CYP17, CYP11B1, and CYP11B2.[92] Ketoconazole is licensed as an orphan drug for CS in Europe but is used “off label” in the management of Cushing patients in the United States. It interacts with medications metabolized through or modulating the activity of the CYP3A4 enzyme, and interaction with concomitant treatments should be taken in account. Hepatic toxicity should be monitored, as mild elevation of transaminase can occur, mostly in the first months of treatment. Pending regular monitoring, it is generally asymptomatic and reversible on drug discontinuation. The drug is given twice or thrice daily orally, and the starting dose is usually 400 mg/day, which can be increased to up to 1200 mg/day. More recently, a stereoenantiomer of ketoconazole, levoketoconazole, has been used to treat CS.[93]

Metyrapone. Metyrapone decreases cortisol synthesis by inhibiting 11β-hydroxylase (CYP11B1 and CYP11B2), the last enzyme involved in cortisol biosynthesis. It is licensed for CS in Europe but is used “off label” in the management of Cushing patients in the United States. The half-life is short, requiring multiple (generally three to four) doses per day, taken orally. The starting dose is 500 to 750 mg/day, and the maximum dose is 4000 mg/day.[92] Metyrapone can cause adrenal insufficiency, dizziness, nausea, and dyspepsia, which are often reversible on dose reduction. Taking the medication with food may reduce gastrointestinal symptoms. Accumulation of adrenal steroid precursors with mineralocorticoid activity may occur, but probably less than in Cushing disease, leading to hypertension, edema, or hypokalemia.

Osilodrostat. Osilodrostat decreases cortisol biosynthesis by inhibiting 11β-hydroxylase (CYP11B1 and CYP11B2), similar to metyrapone. Its affinity for the enzyme is higher, and its half-life is longer. Osilodrostat has been recently approved in the United States and in Europe for the treatment of CS. Experience in adrenal Cushing is limited, as most trials have only involved patients with Cushing disease.[94] The starting dose for osilodrostat is 2 mg, twice daily, taken orally, and can be increased up to 30 mg two times a day. Osilodrostat can interact with drugs metabolized by CYP3A4, CYP1A2, CYP2C19, and CYP2D6, and interaction with concomitant treatments should be taken in account. Furthermore, medications that are associated with QT prolongation are not recommended, because minor QT prolongation has been observed.[92]

Mitotane. o,p’-DDD (ortho, para’, dichloro-, diphenyl-, dichloro ethane; mitotane) is approved for the treatment of ACC. It inhibits steroid synthesis by acting on multiple steroidogenic enzymes, including CYP11A1, 3β-HSD, CYP11B1, and CYP11B2. Interestingly, o,p’-DDD also has a cytotoxic effect on adrenocortical cells that is important for its use in ACC. It is usually effective for controlling steroid excess in patients with secreting ACCs. The treatment is given orally, thrice daily, at a dose of 1.5 to 9 g/day. Tolerance and mitotane blood levels need to be carefully monitored to adjust the daily dose. A mitotane blood level of at least 14 mg/L seems to improve the tumor response rate.[95] However, the side effects of mitotane (mainly digestive and neurologic) often limit the ability to reach this suggested optimal level. The daily mitotane dose required to achieve this 14 mg/L level varies from patient to patient. Therefore, close monitoring of mitotane blood levels is very helpful to remain in the narrow range between 14 to 20 mg/L, considered by most authors to be the therapeutic range for mitotane in ACC. Because o,p’-DDD can induce adrenal insufficiency, glucocorticoid substitution is systematic, and mineralocorticoid therapy should be discussed. Because mitotane induces CYP3A4, it can inactivate hydrocortisone substitution therapy, and the substitutive dose is usually much higher than that used in other causes of adrenal insufficiency.[96]

Other Medical Treatments for Adrenal Cushing Syndrome. In rare patients with severe adrenal Cushing that is difficult to control, which is mostly observed in the context of ACC, the glucocorticoid receptor antagonist mifepristone has been used. For patients who are unable to take an oral drug and whose condition is severe, intravenous etomidate has been used.[73]

Patients with CS comorbidities including hypertension or diabetes need specific treatment for their comorbidities along with treatment of cortisol excess. In cases of mild autonomous cortisol secretion, as discussed below, treatment of comorbidities can be a first step before deciding whether or not to formally treat adrenal cortisol excess. In patients with overt CS, even though cortisol control will lead to improvement of comorbidities in most patients, persistence of these comorbidities is also frequent, and therefore long-term monitoring and specific treatment are important to reduce long-term morbidity and mortality.[67]

Surgery

Surgery is the main treatment for unilateral tumors causing CS.[97] For benign adenomas this is achieved by a laparoscopic approach, with a low complication rate.[98] For adrenal cancer it is performed by a conventional transabdominal approach, although for small ACCs laparoscopic surgery by an expert adrenal surgeon may be an option,[99] always keeping in mind a R0 resection is crucial to improve the prognosis of such an aggressive cancer. For bilateral tumors, laparoscopic adrenalectomy is also discussed in overt Cushing. In patients with PPNAD, adrenalectomy is in most cases bilateral, as good control of CS has rarely been reported after unilateral adrenalectomy.[100] In PMAH, despite the disease being bilateral in most cases, the possibility of unilateral adrenalectomy is discussed to avoid permanent adrenal insufficiency.[101] In ACA and PMAH, the therapeutic choice needs to take in account the level of cortisol excess. There is no doubt that patients with overt Cushing need specific treatment to control cortisol excess. However, in patients with possible MACE, which is most frequently diagnosed in patients with ACA or PMAH, the treatment is discussed on an individual basis.[63] When unilateral ACAs are not treated surgically, worsening of autonomous cortisol secretion or tumor growth during follow-up is rare.[102] However, diabetes, obesity, hypertension, and dyslipidemia seem to worsen with time. Most retrospective studies suggest that surgery for ACA causing mild autonomous cortisol secretion can improve diabetes or hypertension.[103] In this situation, the comorbidities that may be a consequence of cortisol excess are important to consider. Patient history, age, and individual factors that could play a role in the comorbidities and the persistence of hormonal alterations are important parameters to take in account in the surgical indication. For PMAH, the consensus is that bilateral adrenalectomy should not be offered to patients with MACE.[63] However, unilateral adrenalectomy could be discussed. Normalization of urinary cortisol and response to dexamethasone suppression test has been reported after unilateral adrenalectomy in PMAH, and corticotrophin deficiency can also be observed, and is in most cases transient.[104] In PMAH patients with overt Cushing, bilateral adrenalectomy can be discussed, and in small series has proven to be efficient in the long term.[105] However, unilateral adrenalectomy in PMAH with overt Cushing has also been reported in small series to improve cortisol dysregulation, at least transiently, with the advantage of avoiding definite and complete adrenal insufficiency. In patients with asymmetric adrenal volume, removal of the largest adrenal has been suggested, and the results appear to be associated with the characteristics of the remaining adrenal mass.[104]

Surgery in adrenal Cushing should take the patient's medical condition into account in order to prevent perioperative complications. Diabetes, hypertension, or hypokalemia will require specific treatment to improve patient's condition before surgery and during the perioperative period.[106] Diabetes and cortisol excess increase the risk of infection and can delay wound healing. *Pneumocystis jiroveci* infections can be observed during treatment of severe hypercortisolism, and prophylactic trimethoprimsulfamethoxazole can be administered.[2] In cases of very severe cortisol excess with major clinical complications, steroidogenesis inhibitors may be given in preparation for surgery. However, in patients with ACC, presurgical administration of steroidogenesis inhibitors should not significantly delay removal of the malignant tumor. Cushing patients are at higher risk of venous thrombosis, therefore perioperative thromboembolic prophylaxis is very important.

Successful adrenal surgery for adrenal CS will almost always induce immediately adrenal insufficiency. This is obvious for bilateral adrenalectomy, but will also occur almost in all cases after unilateral adrenalectomy. In this situation, hypercortisolism suppresses the hypothalamic–pituitary–adrenal axis, and at the time of adrenal tumor removal endogenous cortisol levels become low or undetectable. It is therefore mandatory to start glucocorticoid substitution by intravenous administration of hydrocortisone at the time of surgery, and as soon as the patient can take oral medications, switch to an orally administered stress dose that is tapered down to a physiologic dose before cortisol levels are assessed. Steroid withdrawal symptoms can occur after correction of cortisol excess. Increasing the dose of hydrocortisone may reduce these symptoms; however, this should be avoided in the long term, because glucocorticoid overdosage will limit improvement after Cushing treatment and impair the possibility of recovery from adrenal insufficiency.

PERSPECTIVES

Investigation of patients at high risk (metabolic syndrome, psychiatric disorders, low bone density in young adult patients, and so on) is important to rule out CS. Although the Endocrine Society recommends the first-line screening test, the choice is dependent on expert understanding and on the patient's clinical presentation. Improvements in the sensitivity and specificity of screening tests are fundamental for the diagnosis. Structurally based assays, such as LC-MS/MS, have only recently become available for clinical practice and are probably the most accurate methodologies.

Although the precise sequence of events and the molecular mechanisms underlying the role of PKA pathway in causing adrenal CS are not fully understood, the central role of abnormal PKA activation in cortisol hypersecretion has been well established through both cellular and murine models. Accordingly, genetic alterations affecting key regulatory members of the PKA signaling pathway, such as *PRKACA*, *PRKAR1A,* and the *PDE* genes, are the most frequent mutations identified in CPA and PPNAD. However, the molecular relationship between the inactivating *ARMC5* mutations identified in 40% of cases of PMAH and the more moderate activation of PKA signaling observed in these hyperplasias remains to be elucidated. Altogether, genomic studies and omics approaches have then allowed the identification of genetic causes of more than 50% of cortisol-producing ACTs, but it is important to understand the genetic origin of the remaining tumors. Indeed, studies of the genes affected in these tumors through the characterization of cellular and mouse models containing these alterations have drastically improved our understanding of the physiopathology of ACTs, but also of the control of adrenocortical homeostasis. Finally, based on these data, one important perspective is to develop new treatments for cortisol-producing ACTs that could first be tested in mouse models that best reproduced human adrenocortical disease.

The management of patients with MACE and the benefit of adrenal surgery need to be demonstrated in prospective studies. The potential role of medical treatment in inhibiting cortisol secretion or antagonizing the glucocorticoid receptor need to be investigated in MACE due to unilateral or bilateral ACTs.

The role of MACE in the development of comorbidities need to be better understood and demonstrated, as well as the potential genetic factors that could explain an increased susceptibility to the consequences of cortisol dysregulation. This would help to identify patients who would benefit from treatment of MACE.

Prognostication for adrenal cancer and novel therapies for progressing tumors are urgently needed. The genetic causes of bilateral adrenal tumors remain to be established for most PMAH patients and some PPNAD patients. The development of specific medical treatments targeting genetic defects in signaling pathways would be appealing.

The benefit of unilateral versus bilateral adrenalectomy in PMAH needs to be demonstrated, and the potential role of medical treatments needs to be investigated in clinical trials.

EPIDEMIOLOGY

KEY POINTS

- Adrenocortical carcinoma (ACC) is a rare malignancy that can occur at any age, with a maximum incidence around the fourth to fifth decade.
- In adults, ACC rarely presents as a part of an inherited tumor syndrome, in contrast to children, in whom ACC frequently arises from germline mutations (e.g., *TP53* mutation in Li–Fraumeni syndrome).

Benign adrenal tumors are one of the most common human neoplasias. with a prevalence of greater than 4% in computed tomography (CT) studies.[1] In contrast, adrenocortical carcinoma (ACC) is a rare malignancy, with an incidence of 0.7 to 2 per million population per year.[2,3] An unusually high incidence of ACC has been found in children in southern Brazil (3.4–4.2 per 1 million children vs. an estimated worldwide incidence of 0.3 per 1 million children) and is related to the high prevalence (0.27%) of a specific germline *TP53* pathogenic variant (p.R337H) that is likely to have low penetrance.[4] ACC is more frequent in women than in men (ratio: 1:1.5). The incidence peaks around the fourth and fifth decade, but the tumor can appear at any age.[5]

RISK FACTORS AND GENETICS OF ADRENOCORTICAL CARCINOMA

There are no established environmental risk factors associated with an increased risk of developing ACC. There is a predilection for the female sex, which does not influence any clinical decision-making in terms of prevention, diagnosis, or therapy. Several hereditary tumor syndromes are associated with an increased risk for ACC. However, the absolute risk is still rather low. In Li–Fraumeni syndrome[6] the frequency of ACC is as high as 4%,[7] mostly affecting children younger than 18 years of age. Up to 80% of children with a diagnosis of ACC harbor a *TP53* pathogenic germline variant, and 4% of adult patients with ACC carry a germline *TP53* pathogenic variant.[8,9] Lynch syndrome, also known as hereditary nonpolyposis colon cancer, has been found to be predisposing condition in another 4% of cases of adult ACC.[9] Screening for Lynch syndrome can be conducted by staining for the four Lynch syndrome–associated gene products by immunohistochemistry of the tumor and microsatellite instability testing. Patients with multiple endocrine neoplasia 1 (MEN1) have a higher risk for adrenal tumors, including ACC. ACC cases have been reported in the context of familial adenomatous polyposis, providing molecular evidence of an involvement of WNT/β-catenin signaling in ACC pathogenesis. ACC can also be a part of Beckwith–Wiedemann Syndrome and has been described in cases of Carney complex.[10] Overall, a familial cancer syndrome can be observed in up to 10% of patients with ACC, and therefore a detailed family history can further streamline genetic testing, which should be considered in any ACC patient for *TP53* (Li–Fraumeni syndrome) and, depending on other information from tumor analysis or family history, for *MSH2*, *MSH6*, *MLH1*, and *PMS2*, as well as *MEN1*, *APC*, and *PRKAR1A*. Identifying a predisposing germline variant will further inform treatment (e.g., immunotherapy for Lynch syndrome, caution regarding radiation therapy for Li–Fraumeni syndrome), set the basis for family cascade testing, and define future surveillance for cured patients and at-risk family members.

Tumor testing for somatic variants provides insight into potential therapeutic targets. However, there is only limited evidence to recommend this as a diagnostic procedure. However, future individualization of therapy may be based on individual tumor profiles, e.g., CDK4/6 inhibition (for *CDKN2A*-mutated tumors) or immunotherapy for patients with Lynch syndrome, hypermutated, or microsatellite unstable tumors.

CLINICAL PRESENTATION

KEY POINTS

- Approximately 50%–60% of patients present with signs or symptoms related to overproduction of adrenal steroid hormones.
- Patients with hormonally nonfunctioning adrenocortical carcinoma (ACC) report symptoms of abdominal discomfort or back pain due to the large tumor size (the median diameter of ACC at diagnosis is 11 cm).

In approximately 10% of patients, ACC is detected incidentally during imaging for other purposes.

Most adult patients with ACC (50%–60%) present with signs and symptoms of adrenal steroid excess, and this percentage is much higher in children (>85%).[11,12] Rapidly progressing Cushing syndrome with or without virilization is the most frequent presentation. Androgen-secreting ACCs in women present with hirsutism and virilization with male pattern baldness and oligoamenorrhea of recent onset. Estrogen-secreting tumors in males lead to gynecomastia and testicular atrophy. Rare aldosterone-producing adrenocortical carcinomas present with severe hypertension and profound hypokalemia.[13] However, low serum potassium is more often the result of excessive cortisol production leading to incomplete renal inactivation by 11-β-dehydrogenase type 2 with consecutive apparent mineralocorticoid excess. In addition, ACC patients with elevated aldosterone levels and hypokalemia often have a hyperreninemic state suggested to arise from compression of the renal parenchyma and vasculature by the often large adrenal tumor.[14]

Patients with a nonfunctioning ACC usually present with symptoms of abdominal discomfort (nausea, vomiting, abdominal fullness) or back pain caused by the large tumor mass. Tumor invasion into the inferior vena cava is not uncommon and may lead to complaints suggestive of deep vein thrombosis and lower extremity edema. Extension to the level of the right atrium may induce shortness of breath and be paralleled by pulmonary tumor emboli. Due to more frequent and improved abdominal imaging, an increasing percentage of ACC is discovered incidentally. Nonspecific symptoms such as fever, weight loss, and loss of appetite are rare.[15] In fact, patients may carry a large tumor burden without much evidence of systemic disease besides signs and symptoms of hormone excess.

KEY POINTS

- Comprehensive assessment of hormonal activity is mandatory in suspected adrenocortical carcinoma (ACC) for optimal perioperative management and for monitoring during follow-up.
- Cross-sectional imaging using computed tomography (unenhanced and delayed postcontrast imaging) or magnetic resonance imaging (with chemical shift) are frequently able to provide hints to the diagnosis of ACC prior to surgery.
- (^{18}F)-fluorodeoxyglucose positron emission tomography can provide valuable information in patients with indeterminate conventional imaging results or when soft tissue or bone metastases are suspected.
- Weiss score is the most commonly used diagnostic criterion for ACC and must be reported along the other prognostic factors, including resection margin and Ki67 index, to guide further treatment.
- Determination of tumor stage provides the basis for further treatment and carries major prognostic information.

DIAGNOSIS

Hormonal Evaluation

Detailed hormonal evaluation must be performed prior to surgery for ACC to identify tumor markers for long-term follow-up and to guide perioperative treatment strategies (e.g., replacement of glucocorticoids after removal of a cortisol-secreting ACC). Guidance for hormonal evaluation in suspected or established ACC has been provided by the European Society for Endocrinology and the European Network for the Study of Adrenal Tumours (Table 98.1). High testosterone levels in women or high estradiol in men, or cosecretion of glucocorticoids and sex hormones, is indicative of a malignant adrenal lesion. In addition, benign cortisol-producing adrenocortical tumors very often show low dehydroepiandrosterone sulfate (DHEAS) concentrations (as a result of suppressed adrenocorticotropic hormone drive), whereas highly elevated DHEAS is suggestive of ACC. Similarly, high levels of steroid precursors, particularly 11-deoxycortisol, are often observed in seemingly hormonally-inactive ACCs. In our experience, autonomous hormone secretion can be detected in greater than 80% of adult patients and in an even higher percentage of children with ACC.[11,12] When using liquid chromatography tandem mass spectrometry–based methods in almost all patients with ACC, steroid or its metabolites can be detected in plasma or urine.[16] Therefore, in large, apparently nonfunctional tumors, measurement of urinary or plasma metanephrines is mandatory prior to surgery to exclude a pheochromocytoma.

TABLE 98.1 Diagnostic Workup in Patients With Suspected or Proven Adrenocortical Carcinoma*

Hormonal Workup	
• Glucocorticoid excess	- Dexamethasone suppression test (1 mg, 2300 h) - 24-h urine cortisol - Basal ACTH (plasma)
• Sexual steroids and steroid precursors	- DHEAS (serum) - 17-OH-progesterone (serum) - Androstendione (serum) - Testosterone (serum, only in women) - 17-beta-estradiol (serum, only in men and postmenopausal women) - 11-deoxycortisol
• Mineralocorticoid excess	- Potassium (serum) - Aldosterone/renin ratio (only in patients with arterial hypertension and/or hypokalemia)
• Exclusion of a pheochromocytoma	- Fractionated metanephrines in 24-h urine or free plasma metanephrines
Imaging	- CT or MRI of abdomen and pelvis and CT chest - FDG-PET (optional) - Bone scintigraphy or brain imaging (when skeletal or brain metastases are suspected)

ACTH, Adrenocorticotropic hormone; *DHEAS*, dehydroepiandrosterone sulfate; *CT*, computed tomography; *MRI*, magnetic resonance imaging; *FDG-PET*, (^{18}F)-fluorodeoxyglucose positron emission tomography.
*Recommendations of the ACC Working Group of the European Network for the Study of Adrenal Tumors (ENSAT), May 2005.

Imaging

Imaging plays a key role in the diagnostic workup of patients with suspected adrenal malignancy. Together with a careful endocrine workup, modern cross-sectional imaging is able to correctly diagnose an adrenal mass as ACC prior to surgery in the majority of cases. Size is an obvious criterion, and for an adrenal mass greater than 6 cm, the likelihood of ACC increases dramatically.[17] In the German ACC registry (n = 1540), the median tumor size at diagnosis was 10.9 cm (range 2.3–40 cm). Thus, in many patients, size alone is a strong indicator of malignancy. However, stage I ACC with a diameter of less than 5 cm has the best prognosis, and it is therefore important to identify adrenal malignancy as early as possible. Thus, tumors between 3 and 8 cm represent a major diagnostic challenge. In children younger than 15 years of age, every adrenal mass is suspicious of malignancy, although no formal imaging studies on this population have been performed.

Currently, no single imaging method can unequivocally determine that an adrenal mass is ACC. The imaging criteria with best evidence

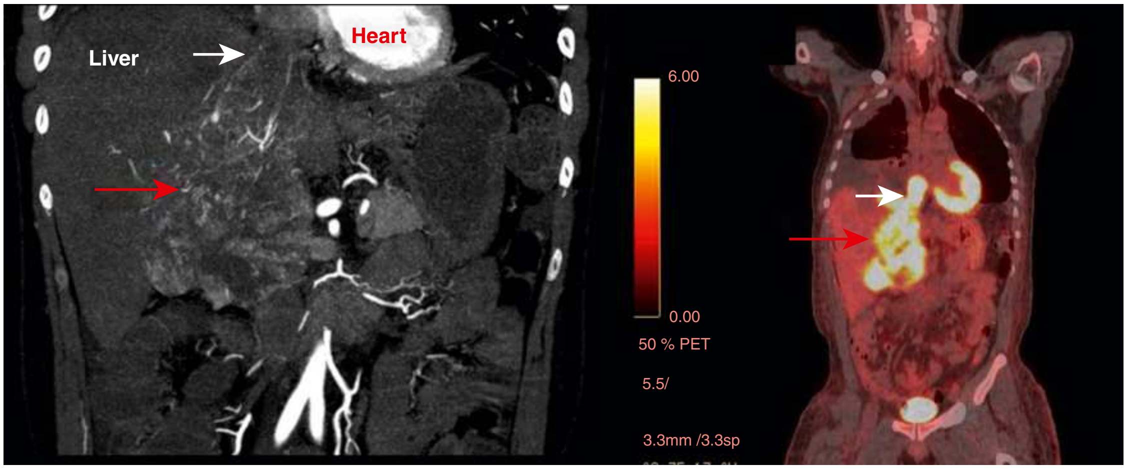

Fig. 98.1 **Coronal images from computed tomography (CT) with intravenous contrast (left) and FDG-PET/CT (right) of a 50-year old male patient with locally advanced right-sided adrenocortical carcinoma *(red arrow)* with extension to the inferior vena cava *(white arrow)* and right atrium.**

is using a threshold of less than or equal to 10 Hounsfield units (HU) in unenhanced CT for the diagnosis of a benign adrenal lesions (for review, see[18,19]).

However, lipid-poor benign adenomas are frequent and show unenhanced HU values greater than 10 [20] and thus are indistinguishable from ACCs. In these cases, delayed postcontrast CT with calculation of the percentage washout for adrenal masses at 10 to 15 minutes or magnetic resonance imaging (MRI) including chemical shift are reasonable "second-line" imaging methods. It is important, however, to recognize that all these imaging characteristics can only be applied to tumors with a homogeneous appearance. Heterogeneous masses and masses that remain indeterminate represent at least 20% of all adrenal tumors (and are even more common amongst larger tumors), necessitating additional diagnostic work-up, such as (^{18}F)-fluorodeoxyglucose positron emission tomography (FDG-PET) imaging.[21,22] In patients with low risk for an ACC, follow-up imaging after 6 to 12 months can be performed.[23]

Multiplanar MRI is particularly suited to separating adrenal masses from surrounding structures like liver, spleen, pancreas, and kidney and often gives a better evaluation for vascular structures, such as adrenal, renal, and cavernous vein. Preoperative CT can be combined with chest imaging for the presence of metastatic disease. Ultrasound techniques (including contrast-enhanced methods) have not been thoroughly investigated but may be particularly valuable for the detection of liver metastases and during follow-up in selected patients. It has been shown that FDG-PET is highly valuable in the differential diagnosis of indeterminate adrenal masses, and while most ACCs show a high FDG signal and most adenomas show a low FDG signal, approximately 10% of tumors in each group show discordance[24,25] (Fig. 98.1). This is particularly important for the positive predictive value, taking into consideration the much higher prevalence of benign adrenal tumors. In addition to 10% of benign adenomas, pheochromocytomas also show uptake of FDG, and in our experience 5% to 10% of primary ACCs are FDG-PET–negative. Imaging with FDG also has the advantage of simultaneously detecting metastases at other sites, but metastatic lesions less than 1 cm (particularly in the lung) can escape detection by FDG,[26,27] indicating that PET cannot substitute for CT imaging.

Fine-needle biopsy as a differential diagnostic tool is rarely helpful, as the diagnostic accuracy is often low.[28,29] In addition, there can be significant complications, as it violates the tumor capsule, which is not in accordance with the usual oncological principle of ACC surgery, which aims to remove tumor in its entirety.

Staging at the time of diagnosis should include high-resolution CT of the chest (in addition to abdomen and pelvis) for early detection of lung metastases. Specific imaging of brain and bones is only needed in case of clinical suspicion. There is some evidence that FDG-PET/CT can improve staging at initial diagnosis or during follow-up.[25-27]

Histopathology

The pathologic diagnosis of ACC can be difficult due to the lack of clear-cut morphologic criteria,[30] and it is recommended to involve a specialized pathologist. In the German ACC registry, the initial histopathologic diagnosis was changed in 13% of cases by the reference pathologist.[31]

Different diagnostic scores have been introduced to diagnose malignancy. The Weiss system[32] is the most widely used and combines nine morphologic parameters related to tumor structure, cytologic features, and tumor invasion. Further morphologic parameters of importance are broad fibrous bands and hemorrhage. An altered reticulin framework is typical for ACC, and together with the necrosis, high mitotic rate, and vascular invasion, it may become a reliable and more reproducible tool for the diagnosis of malignancy than the Weiss score.[33] Careful assessment of the resection status (R0, R1, R2) is also of great importance, as it defines further treatment strategies. For the same reason, violation of the tumor capsule must be reported.

Important information is provided by immunohistochemistry. Here, Ki67 expression carries highly important prognostic information and must be part of the pathological report. In ACC, a Ki67 labeling index of greater than or equal to 20% is associated with poor clinical outcome.[34] Although there are several markers, such as melan A and inhibin-alpha, SF1 has emerged as the single most useful marker to define the adrenocortical origin of the tumor. ACCs are typically negative for chromogranin A and S100.[30,35-37]

STAGING

The most commonly used tumor-node-metastasis classification is the European Network for the Study of Adrenal Tumors (ENSAT) classification (Table 98.2). In this staging system, stage III is defined by tumor infiltration in surrounding tissue or in adjacent organs or tumor thrombus in vena cava/renal vein or positive lymph nodes, whereas stage IV is defined by the presence of distant metastasis.[38] The

ENSAT staging system provides a powerful prognostic tool for predicting both disease-free and disease-specific survival in patients with ACC (Fig. 98.2) and has been confirmed to be superior to the 2004 Union for International Cancer Control classification.[39] In addition to staging, other pathological and clinical factors influence the long-term outcomes and prognosis. In addition to the prognostic role of Ki67%, in patients with stage I, II, or III who had complete surgical resection, cortisol overproduction has been associated with shorter time to recurrence and shorter overall survival compared to non–cortisol–producing ACCs.[40]

GRAS (Grade, Resection status, Age, and Symptoms) parameters have been used to further predict ACC prognosis and outcomes. In patients with resectable ACC (mostly stages I–III), high GRAS score is associated with poor prognosis.[41,42] Similarly, in patients with advanced ACC at diagnosis (stages III and IV), utilizing GRAS score in addition to staging provided a clinically useful tool to predict prognosis.[43]

TABLE 98.2 Staging System for Adrenocortical Carcinoma: ENSAT 2008

Stage	ENSAT 2008
I	T1, N0, M0
II	T2, N0, M0
III	T1–2, N1, M0
	T3–4, N0–1, M0
IV	T1–4, N0–1, M1

ENSAT, European Network for the Study of Adrenal Tumor; *T1,* tumor ≤5 cm; *T2,* tumor >5 cm; *T3,* tumor infiltration of surrounding tissue; *T4,* tumor invasion of adjacent organs, venous tumor thrombus in vena cava/renal vein; *N0,* no positive lymph nodes; *N1,* positive lymph node(s); *M0,* no distant metastases; *M1*, presence of distant metastasis.

From Fassnacht M, Johanssen S, Quinkler M, et al. Limited prognostic value of the 2004 International Union Against Cancer staging classification for adrenocortical carcinoma: proposal for a revised TNM Classification. *Cancer*. 2009;115:243–250.

KEY POINTS

- Surgery for adrenocortical carcinoma (ACC) should be performed by an expert surgeon aiming at an R0 resection in both primary and recurrent ACC.
- Medical treatment with mitotane may be useful both as adjuvant therapy and in advanced disease. It requires drug monitoring (target concentration ≥14 mg/L) and adequate steroid replacement.
- Radiation therapy may be used as an adjuvant measure in selected patients with positive margins after surgery or as a palliative treatment option in select patients with advanced ACC.
- First-line cytotoxic therapy in adults with advanced ACC consists of etoposide, doxorubicin, and cisplatin plus mitotane. No standard protocol is established in children.
- Targeted therapies for ACC have not yet shown activity superior to cytotoxic chemotherapy. Similarly, checkpoint inhibitors have yielded heterogeneous results and are only successful in a subset of patients.

THERAPY (FIG. 98.3)

Surgery

Most patients with ACC are diagnosed at stages I to III (see Fig. 98.2). In these stages, complete tumor removal is the single most important therapeutic measure and offers the best chance for cure. All available data indicate that surgery should be performed by an experienced surgeon who is aware of the pitfalls of surgery for ACC (violation of the tumor capsule, tumor spillage). An R0 resection (resection margins microscopically tumor-free) is of utmost importance to improve long-term prognosis. To achieve this goal, sometimes surgery needs to be extensive, with *en bloc* resection of invaded organs. Tumor spillage during surgery is a key factor in upgrading to stage IV and poor prognosis.[38] The presence of a tumor thrombus is compatible with complete tumor resection but occasionally necessitates a cardiac bypass technique.[44] Several reports have analyzed the value of laparoscopic adrenalectomy in ACC. Considering the retrospective nature of the reports and the potential biases, open adrenalectomy is still regarded as standard treatment for ACC, and laparoscopic surgery

by an experienced team can be an option when the primary adrenal mass diameter is less than 6 cm without evidence of local invasion or lymphadenopathy.[21,22,45]

The role of localized lymph node dissection (LND) is evolving. The results of a retrospective analysis of 283 patients with stage I to III ACC suggest that locoregional LND can improve both diagnostic accuracy and therapeutic outcome.[46] In multivariate analyses, a significantly reduced risk for tumor recurrence (hazard ratio [HR] 0.65) and disease-related death (HR 0.54) was found in LND patients compared with non-LND patients. In contrast, systematic ipsilateral nephrectomy in the absence of gross local invasion is probably not of benefit.[47]

The role of surgery in recurrent or metastatic disease is ill-defined. Several studies have addressed this issue.[47-52] Based on these studies, surgery for recurrent ACC can be performed in patients with a disease-free interval of preferably more than 12 months, in whom a complete resection is feasible and in the setting of an experienced multidisciplinary team. It is expected that patients with small-volume metastatic disease and adequate performance status will have a survival advantage over patients with unresectable metastases and poor performance status.[53] However, we advocate against surgery if the time between surgery and recurrence is less than 6 months, as these patients often require systemic therapy options. In all other patients, an individualized decision is required, and they may be candidates for a combined approach of systemic therapy and/or ablative procedures (e.g., radiofrequency ablation, chemoembolization).

Radiation Therapy

There is a general assumption that ACC is not a radioresistant malignancy.[54] Over the past two decades, there have been multiple retrospective studies of relatively small number of patients showing conflicting evidence about the use of adjuvant radiation therapy in ACC. In general, adjuvant radiation therapy is viewed as a tool to reduce local recurrence when resection margins are microscopically positive (R1), while the routine use of adjuvant radiation therapy is not recommended when the surgical margins are negative (R0).[21,55] A commonly used regimen that utilizes a fractionation scheme with single doses of 1.8 to 2.0 Gy for 5 days per week for 5 to 6 weeks is recommended. The total dose should not fall below a minimum of 40 Gy, and ideally should reach 50 to 60 Gy.

Palliative radiotherapy in symptomatic metastatic lesions is a well-established treatment option for patients with ACC, in particular for bone metastases. Palliative radiotherapy with limited doses may also be effective in unresectable abdominal recurrences or symptomatic metastases causing pain and vascular or intestinal obstruction. For optimum results of radiotherapy in ACC, an experienced radiotherapist using modern treatment concepts with CT planning, high-voltage radiation, and multiple fields is a prerequisite.

MEDICAL THERAPY

Mitotane

Mitotane (1.1 dichloro-2(o-chlorophenyl)-2-(p-chloro-phenyl) ethane, o,p'-DDD) is an adrenolytic compound with specific adrenolytic activity that was introduced in the treatment of ACC more than 60 years ago. Its precise mechanism of action is not fully understood. Its therapeutic activity depends on metabolic activation in adrenocortical cells. Mitotane is hydroxylated in the mitochondria and transformed into an acyl-chloride. The activated metabolites may directly bind to macromolecules, thereby inhibiting their activity and inducing oxidative damage through production of free radicals.[56] More recently, mitotane adrenolytic activity has been linked to increasing endoplasmic reticulum stress secondary to the inhibition of sterol-O-acyl-transferase 1, leading to the accumulation of toxic intracellular lipids in the adrenal cortex.[57] In addition to its adrenolytic activity, mitotane has an inhibitory effect on steroidogenesis, which adds to its value in the management of patients with hormonally functional ACCs.

Despite the lack of randomized trials, there is evidence that mitotane can induce significant tumor regression in up to 25% of cases with metastatic ACC and achieve control of hypercortisolism in most patients.[58,59] Complete responses have been described, and long-term survival is seen in the occasional patient, but is the exception, not the rule.

In the adjuvant setting, a large retrospective analysis has indicated that mitotane holds great potential to prolong disease-free survival and overall survival in ACC.[60] Nonetheless, it remains a matter of discussion whether adjuvant mitotane is of long-term benefit for all patients.[61] Two randomized studies were launched to explore the role of adjuvant mitotane alone or in combination with chemotherapy in ACC. The ADIUVO trial aims to compare adjuvant mitotane use with a strategy of "watchful waiting" in patients with low or intermediate risk for recurrence (i.e., defined by R0 resection, absence of metastases, and a Ki67 ≤10%). More recently, the ADIUVO-2 study started enrolling high-risk patients, defined as having stage I to III with Ki67 greater than 10%. Patients will be randomized to adjuvant mitotane for 2 years versus adjuvant mitotane for 2 years combined with 3 months of cisplatin and etoposide.

Mitotane is given as 500-mg tablets. Monitoring mitotane blood concentrations is essential for providing optimal efficacy and reducing toxicity. Treatment aims at mitotane concentrations above 14 mg/L for an antitumor response. Higher concentrations (>20–30 mg/dL) can be associated with more adverse effects, whereas a response is less likely at a concentration less than 14 mg/L. Thus, mitotane has a narrow therapeutic window. However, some patients may respond to lower mitotane concentrations. Due to the long half-life of mitotane, target levels are often achieved only after weeks to months of therapy.[62] Treatment is often initiated with 1.5 g/day and rapidly increased to 4.5 to 6 g/day until target concentrations have been reached. While most adverse effects are related to mitotane plasma concentrations, adverse gastrointestinal effects such as diarrhea seem to be more related to the daily dose. During long-term treatment, the dose of mitotane can usually be reduced, and many patients need only 2 to 3 g/day during long-term therapy. Ingestion of mitotane together with a lipid-rich drink or meal may enhance mitotane absorption and decreases gastrointestinal side effects. Due to its adrenolytic activity, mitotane treatment induces adrenal insufficiency. Furthermore, mitotane also increases the metabolic clearance of glucocorticoids by a very strong induction of cytochrome P450 3A4 (CYP3A4) and increases the concentration of cortisol-binding globulin.[63-65] Patients on mitotane often require a higher dose of glucocorticoid replacement (averaging 40–60 mg per day) compared with patients with other forms of adrenal insufficiency (average requirements approximately 15–30 mg per day). Insufficient glucocorticoid replacement enhances mitotane intolerance. Aldosterone secretion is less often affected, as mitotane primarily acts on the zona fasciculata and the zona reticularis. However, aldosterone secretion should be monitored, and replacement with fludrocortisone may become necessary with long-term use of mitotane. In addition, mitotane increases sex hormone–binding globulin[63] and often leads to low free testosterone concentrations in males. With long-term therapy, free thyroid hormone concentrations decline in the presence of low to low-normal thyroid-stimulating hormone, suggesting secondary hypothyroidism. Due to its estrogenic activity, mitotane may facilitate the development of gynecomastia.

TABLE 98.3 Recommended Drug Regimens for Advanced Adrenocortical Carcinoma*

Mitotane Monotherapy

In mitotane-naïve patients in good clinical condition and with presumably less aggressive disease:

- Start with 1.5 g/day and increase daily dose within 4–6 days to 6 g/day.
- Measure mitotane blood level every 3–4 weeks.
- Adapt dosage according to tolerability and blood level (maximum dose 12 g/day; most patients do not tolerate >8 g/day).
- In case of relevant adverse effects, lowering the dosage or even interrupting treatment may be required to allow compliance.

For patients in poor clinical condition or with concomitant cytotoxic drugs, a lower dosage (e.g., 3 g/day) is recommended.

Etoposide, Doxorubicin and Cisplatin (EDP) Plus Mitotane (EDP/M)

Every 28 days:

- day 1 40mg/m^2 D
- day 2 100mg/m^2 E
- day 3+4 100mg/m^2 E + 40mg/m^2 P

Plus oral mitotane aiming at a blood level between 14 and 20 mg/L. However, in most patients we do not administer more than 4–5 g/day of mitotane.

In patients unfit for the EDP-M regimen, P-M may constitute a reasonable alternative.

Second-Line/Salvage Therapies

Gemcitabine plus capecitabine

- 800 mg/m^2 gemcitabine on day 1 and 8 (repeated every 3 weeks)
- 1500 mg capecitabine orally per day in a continuous fashion
- additional administration of mitotane should be consideredStreptozotocin plus Mitotane (Sz/M)
- induction: day 1 to 5: 1g Sz/d
- afterwards 2 g/day Sz every 21 days
- plus oral mitotane aiming at a blood level between 14 and 20 mg/L

Gemcitabine plus metronomic 5-fluorouracil or capecitabine as a second-/third-line chemotherapy in advanced adrenocortical carcinoma: a multicenter phase II study. *Endocr Relate Cancer*. 2010;17:445–453

Changes in hepatic gamma glutamyl transaminase levels are so frequent that their absence calls into question patient compliance. However, in some cases, serious hepatotoxicity and even liver failure have been observed. Mitotane prolongs bleeding time, and it is advisable to stop mitotane for a minimum of 1 week prior to major surgery. High low-density lipoprotein cholesterol and/or triglyceride concentrations are regularly observed.[66]

Despite the plethora of adverse effects of mitotane, most patients can be managed with acceptable toxicity in the long term.[67] This is particularly important in an adjuvant setting, as treatment must be given for a minimum of 2 years.

The abovementioned effect of mitotane as one of the strongest available inducers of hepatic CYP3A4[64] has a major impact on the care of ACC patients, because mitotane lowers the blood levels of many frequently coadministered drugs (including but not limited to steroids, antihypertensives, and antibiotics)[65] (Table 98.3).

Cytotoxic Chemotherapy

Only two cytotoxic regimens have been investigated in a randomized controlled trial.[68] This trial, FIRM-ACT, included a total of 304 patients and compared etoposide, doxorubicin, cisplatin, and mitotane (EDP-M) with streptozotocin and mitotane (Sz-M), both as first- and second-line cytotoxic treatment. Although overall survival was not significantly different (14.8 months [EDP-M] vs. 12.0 months [Sz-M]; HR 0.79; $P = 0.07$), objective response rate and progression-free survival clearly favored EDP-M (23.2% vs. 9.2%, $P < 0.001$ and 5.0 months vs. 2.1 months; HR 0.55; $P < 0.001$). Most experts now advocate EDP-M as first-line therapy for patients requiring cytotoxic treatment.[69] Because children were not included in the FIRM-ACT trial, there is no proof that EDP-M is also the first treatment of choice in children, and other regimens might be considered (see Fig. 98.3B).[70]

For patients who fail EDP-M chemotherapy, an individualized approach is needed, with a strong preference for receiving therapy through a clinical trial.[21]

Over the past decade, multiple cytotoxic regimens were reported to have limited efficacy in the management of progressive ACC after failing first-line therapy.

The combination of gemcitabine and capecitabine (or metronomic 5-fluorouracil) has been studied as a second-/third-line regimen based on earlier reports showing disease stabilization for at least 6 months in eight of 28 patients (29%) when using this combination.[71] A more recent report of 145 patients assessed retrospectively after having gemcitabine-based chemotherapy (132 in combination with capecitabine) found more limited impact on survival, with partial responses seen in 4.9% and stable disease in 25% of subjects.[72]

In another retrospective report of 28 patients with advanced ACC who were treated with temozolomide (200 mg/m^2/day for 5 consecutive days every 28-day cycle), median progression-free survival was 3.5 months, with six patients (21%) showing evidence of short-lived objective response, though one subject had complete response to therapy.[73]

Other potential salvage therapies might be trofosfamide or thalidomide. However, both have only modest antitumor activity (150 mg/day).[74,75]

Targeted Therapies

The current success with cytotoxic chemotherapy in ACC is not satisfactory, with less than 50% of tumors responding to treatment, and most of them for only a limited time. Small-molecule multikinase inhibitors (MKIs) have transformed the care of multiple malignancies; however, so far, no breakthrough has been accomplished in ACC.

While the experience with MKIs (e.g., sunitinib, sorafenib, dovitinib, axitinib) has been largely disappointing,[76] it is important to consider multiple factors. First, the patients studied in these trials had virtually all received several different cytotoxic treatments prior to their targeted therapy. Thus, targeted therapies were used as salvage treatment in very high-risk cohorts with poor prognoses. Furthermore, most of these patients had received previous or even concomitant mitotane leading to strong induction of CYP3A4, which frequently plays a major role in the degradation of MKIs and other targeted therapies, thereby profoundly reducing levels of these compounds. Accordingly, studies evaluating earlier treatment with targeted therapies in mitotane-naive patients are urgently needed and may generate an entirely different picture.

c-Met signaling appears to be a worthy target, based on the finding of increased expression of c-Met after exposing an ACC cell line *in vitro* to commonly used treatments in ACC (cisplatin, mitotane, radiation). Thus, it is believed that c-Met signaling could be one of the resistance mechanisms in ACC.[77] In a retrospective report of 16 ACC patients who failed prior therapies, the use of cabozantinib resulted in partial response in three, stable disease in five, and progressive disease in eight patients, with a median progress-free survival of approximately 4 months.[78] Two ongoing phase II trials aim to ascertain the efficacy and safety of cabozantinib in ACC (ClinicalTrials.Gov identifiers: NCT03612232 and NCT03370718).

As ACCs express high levels of insulin-like growth factor (IGF)-2, which acts via the IGF-1 receptor, blockade of the IGF-1 receptor has been studied in ACC. A randomized, phase III trial (139 patients) using the small-molecule IGF-1 receptor inhibitor linsitinib (90 on linsitinib and 49 on placebo) was terminated early due to lack of significant improvement in progression-free survival or overall survival, despite a few patients having an objective response to linsitinib.[79] In a phase I study, the combination of an IGF-1 receptor antibody (cixutumumab) with the mTOR inhibitor temsirolimus led to stable disease for at least 6 months in 11 of 26 patients,[80] whereas other studies exploring monotherapy with the mTOR inhibitor everolimus did not show benefit.[81] Using selective radiopharmaceuticals has been explored in ACC. ^{131}I-iodometomidate binds selectively to adrenal CYP11B enzymes as a targeted radionuclide therapy for advanced ACC. ^{131}I-iodometomidate was given on a compassionate use basis to 11 patients with advanced ACC. One patient experienced a partial response lasting for 26 months, and another five patients had stable disease.[82]

Immunotherapy

In the past decade, the use of immune checkpoint inhibitors has transformed cancer care, and many drugs have been approved to treat different malignancies. The experience with immunotherapy in ACC is evolving, and the results of four small clinical trials were recently published. In a phase Ib clinical trial, avelumab (anti–programmed cell death ligand-1 antibody) was studied in 50 ACC patients, out of whom three (6%) had partial response and 21 (42%) had stable disease. It is important to note that half of the study participants were also on mitotane therapy, including two of the patients who had partial response.[83]

In a phase II clinical trial, nivolumab (anti–programmed cell death-1 [PD-1] monoclonal antibody) was used in 10 ACC patients but had minimal efficacy without objective responses, and only two patients showed stable disease.[84]

Pembrolizumab (anti–PD-1 antibody) was studied in two parallel phase II clinical trials and was associated with partial response rates of 14% to 23%, with reasonable tolerance and low levels of severe adverse events.[85,86]

The role of using immunotherapy with mitotane or MKIs is emerging, and so far there are limited retrospective data to suggest the potential for enhancing the activity of immunotherapy when combined with mitotane or anti–vascular endothelial growth factor therapy.[87,88] These early findings are encouraging to propose future clinical trials combining MKIs or mitotane with immune checkpoint inhibitors.

FOLLOW-UP

Close follow-up is particularly important after seemingly complete surgery for ACC stage I to stage III, as surgery for tumor recurrence is an important treatment option. Initially, staging is repeated every 3 months for a minimum of 2 years (CT of abdomen + chest). Even after 2 years without recurrence, there remains a high risk for relapse. Thus, further follow-up is required, but imaging intervals may increase. Steroid metabolomics are currently being investigated for their potential to detect tumor recurrence early and may lead to less frequent imaging and lower radiation exposure. Regular surveillance of the patient should continue for a minimum of 5 years.

INTRODUCTION AND HISTORY

KEY POINTS

- Pheochromocytomas and paragangliomas are dangerous neuroendocrine (chromaffin cell) tumors that can have lethal consequences if overlooked but are typically curable by surgery.
- Pheochromocytomas, which arise from adrenal medullary chromaffin tissue, are more common (80%–85%) than paragangliomas (15%–20%), which arise from extraadrenal paraganglia.

The term pheochromocytoma derives from the Greek words *phaios* (“dusky”) and *chroma* (“color”); it refers to the staining that occurs when the tumors are treated with chromium salts. The first diagnosis of pheochromocytoma was made in 1886 by Fränkel, and the first large series of successful surgical removals with pharmacologic blockade was reported by Kvale and colleagues in 1956. Pheochromocytomas are rare but treacherous catecholamine-producing tumors that, if missed or not properly treated, almost invariably prove fatal.[1] Prompt initial diagnosis therefore is essential for effective treatment, usually by surgical resection. The clinical manifestations of the tumor are diverse and can mimic a variety of conditions, often resulting in erroneous diagnoses.[1,2]

Pheochromocytomas comprise 80% to 85% of all chromaffin cell tumors and typically arise from adrenal medullary chromaffin tissue. In approximately 15% to 20% of cases tumors arise from extraadrenal paraganglia and are commonly referred to as paragangliomas. Paragangliomas are divided into two groups: those that arise from parasympathetic paraganglia of the skull base and neck (e.g., glomus: caroticum, jugulare, tympanicum, and vagale) as well as anterior mediastinum and those that arise from sympathetic-associated chromaffin tissue. Sympathetic paragangliomas arise from sympathetic ganglia in the abdomen (90%), less commonly from the pelvis, and rarely from the posterior mediastinum (2%). Many abdominal paragangliomas arise from large sympathetic ganglia located around the origin of the inferior mesenteric artery called the organ of Zuckerkandl.[2] Pheochromocytoma occurs at any age, but most often in the fourth and fifth decades, and it occurs equally in men and women. In this chapter, the term “pheochromocytoma” is used to collectively refer to the tumors at both adrenal (pheochromocytoma) and extraadrenal locations (sympathetic paraganglioma), but excluding those at head and neck, as dealt with separately.

Most pheochromocytomas arise sporadically, but up to 35% are hereditary.[3,4] In contrast to sporadic pheochromocytomas that are usually solitary, hereditary pheochromocytomas are often multifocal and bilateral.[5] An early autopsy series indicated a prevalence of pheochromocytoma of 1:1000; significant numbers of tumors remained undiagnosed until death, and up to 50% of these may have contributed to patient mortality.[6] Since then there have been numerous advances in genetics, biochemical diagnosis, localization, and surgical approaches to pheochromocytoma. According to a Dutch nationwide study,[7] there has been an increase in annual incidence of pheochromocytoma to eight cases per million, this presumably reflecting improved detection.

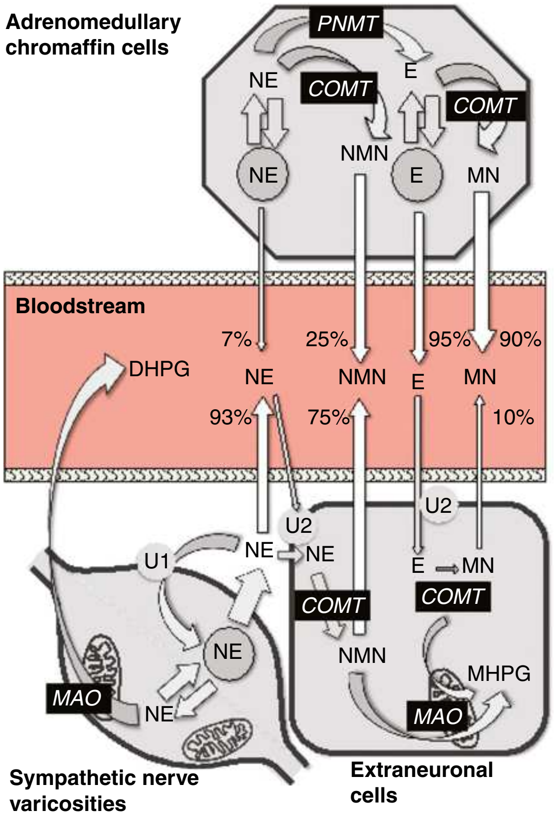

Figure 99.1 Pathways of catecholamine uptake, vesicular storage and leakage, secretion, and metabolism in sympathetic varicosities compared with adrenal medullary chromaffin cells and other extraneuronal cells. *NE*, norepinephrine; *E*, epinephrine; *NMN*, normetanephrine; *MN*, metanephrine; *DHPG*, dihydroxyphenylglycol; *MHPG*, methoxyhydroxyphenylglycol; *PNMT*, phenylethanolamine-N-methyltransferase; *COMT*, catechol-O-methyltransferase; *MAO*, monoamine oxidase; *U1*, uptake 1 (by neuronal transporters); *U2*, uptake 2 (by extraneuronal transporters). Percentages indicate proportions of circulating amines derived from intraadrenal vs. intraneuronal or extraneuronal metabolism. Note: most metabolism occurs initially intraneuronally by deamination of NE leaking from storage vesicles, whereas O-methylation is a relatively minor pathway but important in adrenal chromaffin cells and their tumor derivatives.

CATECHOLAMINE PRODUCTION, SECRETION, AND METABOLISM

KEY POINTS

- The major hormonal products of pheochromocytomas and paragangliomas are the catecholamines, norepinephrine, and epinephrine; these are responsible for most of the clinical signs and symptoms of these tumors.
- Most catecholamines produced by the pheochromocytomas and paragangliomas are metabolized to metanephrines within tumor cells rather than after secretion.

Pheochromocytomas are often described as tumors that secrete catecholamines. The tumors, however, also metabolize catecholamines, and this is a more consistent process than catecholamine secretion (Fig. 99.1).[8] Failure to recognize this key feature probably reflects several misconceptions about the storage and metabolism of catecholamines, perhaps the most pervasive being that metabolism occurs after catecholamine secretion. In fact, substantial amounts of catecholamines are metabolized in the same cells where the amines are synthesized (Fig. 99.1).[9]

Because the enzymes responsible for the metabolism of catecholamines have intracellular locations, the primary mechanism limiting the lifespan of catecholamines in the extracellular space is uptake by active transport, not metabolism by enzymes.[10] Catecholamine metabolism occurs through an array of enzymes, resulting in a variety of metabolites, but in general the most important first step is metabolism within cells of synthesis, and primarily from catecholamines leaking from storage vesicles into the cytoplasm (Fig. 99.1).[9] Most norepinephrine is synthesized within sympathetic neurons; because these neurons contain monoamine oxidase, but not catechol-O-methyltransferase, initial metabolism is by deamination, mainly from leakage of the catecholamine from vesicles and secondly from norepinephrine recaptured after secretion.

In contrast to neurons, chromaffin cells contain catechol-O-methyltransferase so that these cells, unlike neurons, produce methoxytyramine from dopamine, normetanephrine from norepinephrine, and metanephrine from epinephrine (Fig. 99.1).[11] These O-methylated metabolites are produced in small amounts and either only within chromaffin cells after leakage from storage vesicles or in other extraneuronal cells, after uptake following secretion of the catecholamines from sympathetic nerves or the adrenals. The single largest source of O-methylated metabolites represents adrenal chromaffin cells, which account for more than 90% of circulating metanephrine and approximately 25% of circulating normetanephrine (Fig. 99.1).[11] Because these metabolites are similarly produced in chromaffin cell tumors from catecholamines continuously leaking from storage vesicles, a process that is independent of catecholamine secretion, they are superior as diagnostic biomarkers compared with the parent catecholamines.

The final main product of the deamination pathway is vanillylmandelic acid (VMA).[9] Because rates of catecholamine metabolism through the deamination pathway are far larger than for pathways involving extraneuronal and chromaffin cell O-methylation, VMA and other deaminated metabolites are poor biomarkers of catecholamine-producing tumors.

In contrast to norepinephrine and epinephrine, most dopamine in the body is produced in peripheral tissues other than sympathetic nerves and chromaffin cells.[12] Gastrointestinal tissues are a particularly major source of dopamine, large amounts of which are metabolized to sulfate-conjugated derivatives by a specific sulfate-conjugating enzyme confined to these tissues.[13] That same enzyme is also responsible for sulfate conjugation of O-methylated metabolites, which are commonly measured in urine as metanephrines after acid hydrolysis-catalyzed deconjugation; thus, these urinary deconjugated metabolites are largely distinct from the free metanephrines usually measured in plasma. Urinary free dopamine and methoxytyramine are derived from renal uptake and decarboxylation of circulating L-dopa,[14,15] which explains why these metabolites in urine are poor biomarkers of dopamine-producing tumors.

CLINICAL PRESENTATION

KEY POINTS

- The clinical manifestations of a tumor are diverse, variable, and typically non-specific. This can make pheochromocytoma difficult to recognize.
- Signs and symptoms are typically paroxysmal in nature (spells). Spells can occur spontaneously or be triggered by various factors, including certain medications.
- Careful assessment of key signs and symptoms determine the indications for further testing and can assist with interpretation of test results.

TABLE 99.1 Signs and Symptoms of Pheochromocytoma

Symptoms		Signs

Adapted from Lenders et al.[1] and Geroula et al.[16]

Who to Test According to Presentation?

The following patients should be evaluated for a pheochromocytoma: 1) anyone with paroxysmal profuse sweating, pallor, tremor, and tachycardia, especially in a subject with episodic hypertension; 2) as part of routine screening for anyone with a known mutation of one of the susceptibility genes and/or a family history of pheochromocytoma or past history of pheochromocytoma; 3) anyone with an incidentally discovered adrenal mass or mass at an extraadrenal location that may represent a paraganglioma; and 4) anyone who has had episodic hypertension, stroke, tachycardia, or an arrhythmia in response to anesthesia, surgery, medications, or food known to precipitate symptoms in patients with pheochromocytoma (Table 99.1). Among ptients evaluated as part of routine screening or because of an incidentaloma, signs and symptoms of catecholamine excess are not always present or, when present, may be overlooked in part due to their nonspecific nature.[16] Nevertheless, for all presentations, there should be careful consideration of the nature of key signs and symptoms to ascertain or pretest likelihood of disease and thereby further interpret results of subsequent biochemical testing.

Signs and Symptoms

The clinical signs and symptoms related to the presence of pheochromocytoma, as listed in the Table 99.1, result from hemodynamic and metabolic actions of excessive circulating catecholamines and rarely of other amines or cosecreted neuropeptides. Most signs and symptoms considered alone are nonspecific; nevertheless, the episodic presence of palpitations, tremor, and sweating in patients with hypertension with or without pallor should arouse immediate suspicion for a pheochromocytoma, because these symptoms and signs are significantly more prevalent among patients with than without pheochromocytoma.[16] Paroxysmal hypertension is one of the most common clinical signs (40%–50%). The extent of the increase and types of catecholamine secreted, as well as the nature of episodic versus continuous secretion, are important determinants of signs and symptoms. Moreover, adrenoceptor downregulation caused by consistently high circulating catecholamines as well as tumor necrosis or hemorrhage may significantly impact pheochromocytoma-associated elevations in blood pressure. Pheochromocytoma also may present with hypotension, particularly in patients with epinephrine-secreting tumors.

Pheochromocytoma-induced attacks (so-called spells) may usually last from a few seconds to 1 hour, with intervals between attacks varying widely; some occur only once every few months. Initially, the episodes may be mild, of short duration, and infrequent. A typical paroxysm is often characterized by a sudden major increase in blood pressure or heart rate associated with a constellation of one or more signs and symptoms: a severe, often pounding headache; profuse sweating over most of the body, especially the trunk; palpitations with tachycardia; anxiety or a sense of doom; skin pallor, especially on the face; nausea, with or without emesis; and pain in the abdomen, the chest, or both. After an episode, patients usually feel drained, exhausted, and weak, and some may urinate more frequently.

Unusual symptoms related to paroxysmal blood pressure elevations during procedures such as endoscopy or administration of anesthesia (particularly during the induction phase of general anesthesia), or associated with ingestion of food or beverages containing tyramine, should arouse immediate suspicion of pheochromocytoma.[17,18] The use of certain drugs such as metoclopramide, droperidol, glucocorticoids, monoamine oxidase inhibitors, tricyclics and other antidepressants, opiates (e.g., morphine, fentanyl), naloxone, glucagon, certain antibiotics (linezolid), drugs for obesity management (phentermine, sibutramine), and chemotherapy may precipitate a hypertensive episode.[17,18]

Causes of episodic catecholamine secretion often remain unclear, but in some situations a surge in catecholamine secretion may be caused by intentional or accidental tumor manipulation with or without an increase in intraabdominal pressure from palpation, defecation, severe stressful situations, or pregnancy. However, approximately 8% to 10% of patients may be completely asymptomatic; this is often the situation for small (<1 cm) tumors associated with insignificant catecholamine production found during screening or as incidentalomas, but is more often associated with tumors that produce and metabolize but do not secrete catecholamines. In such situations, there may be substantial conversion to metanephrines so that the clinical picture is characterized by an asymptomatic presentation associated with increases in plasma or urinary metanephrines but no or little increase in catecholamines. Other situations include tumors, particularly of the skull base and neck, characterized by the absence of catecholamine-synthesizing enzymes and no production or secretion of catecholamines.

It should also be noted that catecholamines suppress intestinal motility; therefore, severe constipation may occur and occasionally may even cause adynamic ileus. Up to 50% of patients may also present with high glucose levels or even with diabetes mellitus type 2 due to inhibition of insulin secretion via α-adrenoceptors, insulin resistance, and increased glucagon secretion.[19]

Differential Diagnosis

The differential diagnosis of pheochromocytoma includes a long list of conditions that present with signs or symptoms that may also suggest the presence of pheochromocytoma (Table 99.2). Some of these conditions can be excluded readily on the basis of a good history and physical examination. The most common mimic is hyperactivation of the sympathoadrenal axis, which is characterized by hypertension, tachycardia, sweating, anxiety, and increased cardiac output. Sympathetic nervous system activation is characteristic of cardiovascular dysfunction due

TABLE 99.2 Differential Diagnosis for Pheochromocytoma Based on Clinical Presentations

Neuroblastoma, ganglioneuroblastoma, ganglioneuroma
Adrenal medullary hyperplasia
Hyperadrenergic essential hypertension
Baroreflex failure
Thyrotoxicosis
Anxiety, panic attacks
Migraine or cluster headaches
Autonomic epilepsy
Chronic use of amphetamines and steroids
Chronic use of cocaine, tricyclic antidepressants
Chronic use of monoamine oxidase inhibitors
Ingestion of tyramine-containing foods or over-the-counter cold and cough preparations
Hypoglycemia, insulin reaction
Paroxysmal tachycardias including postural tachycardia syndrome
Angina pectoris or myocardial infarction
Mitral valve prolapse
Abdominal catastrophic situations/aortic dissection
Renal parenchymal or renal artery diseases (e.g., stenosis)
Intracranial lesions, cerebral vasculitis, and hemorrhage
Menopausal syndrome
Lead poisoning
Toxemia of pregnancy
Pseudopheochromocytoma
Acute intermittent porphyria

TABLE 99.3 Medications that Are Contraindicated in Patients With Suspected or Proven Pheochromocytoma

Dopamine D2 receptor antagonists	(e.g., metoclopramide, antiemetics)
Sympathomimetics	(e.g., ephedrine)
Nonselective β-adrenoceptor blockers	(e.g. propranolol)
Opioid analgesics	
Noradrenaline reuptake inhibitors	(including tricyclics)
Monoamine oxidase inhibitors	
Corticosteroids	(particularly in high doses)
Peptides	(e.g., adrenocorticotropic hormone, glucagon)
Neuromuscular blocking agents	(used for anesthesia)
Serotonin reuptake inhibitors	(rare)

to various pathologies, but can also occur in patients taking amphetamines (Table 99.3). Blockade of norepinephrine reuptake by antidepressants may also be associated with signs and symptoms similar to those observed with sympathetic nervous system activation. Decreased clearance of released catecholamines can thereby lead to increased plasma or urinary metanephrines (usually normetanephrine). The clonidine suppression test can be useful for some but not all of these patients; in particular, the test is inappropriate in patients taking antidepressants or other drugs that block the uptake of released norepinephrine. Other contraindications include patients with compromised cardiac function.

Another problem involves differentiating patients with pheochromocytoma from those with anxiety, panic attacks, or pseudopheochromocytoma. This generally requires a detailed history and examination, together with close observation of the patient during episodes and biochemical testing. Differentiation from an acute myocardial infarction due to obstructive coronary artery disease may be difficult, because angina pectoris and myocardial damage may occur in the absence of obstructive coronary artery disease in a patient with a pheochromocytoma. Many nonspecific electrocardiographic changes have been reported, as well as various supraventricular and ventricular tachycardias, in patients with pheochromocytoma. In the very rare situation in which a strong discordance is noted between symptoms and laboratory findings, one must consider the possibility of factitious administration of catecholamines that can be diagnosed based on an elevated epinephrine without a concomitant increase in its metabolite, metanephrine.

Biochemical test results that are more suggestive of sympathoadrenomedullary activation than of a tumor (e.g., as occurs in hypernoradrenergic hypertension, renovascular hypertension, congestive heart failure, panic disorder, and dumping syndrome) include proportionally larger elevations of plasma norepinephrine or of epinephrine than of plasma normetanephrine or of metanephrine.[20]

Although severe paroxysmal hypertension should always raise suspicion of pheochromocytoma, it may also reflect a clinical entity called *pseudopheochromocytoma.* Pseudopheochromocytoma refers to individuals (often women) with severe paroxysmal hypertension, whether normotensive or hypertensive between episodes, in whom pheochromocytoma has been ruled out and in whom plasma or urinary metanephrines are usually normal.[21] The most common clinical characteristics of this syndrome may be attributable in many cases to short-term activation of the sympathetic nervous system. Paroxysmal hypertension usually is associated with tachycardia, palpitations, nervousness, tremor, weakness, excessive sweating, pounding headache, feeling hot, and facial paleness or (rarely) redness. In contrast to pheochromocytoma, patients with pseudopheochromocytoma more often present with panic attacks or anxiety, flushing, nausea, and polyuria. Pseudopheochromocytoma is sometimes treatable by antihypertensive drugs or psychotherapy.

One of the most difficult situations for both identifying a pheochromocytoma and patient management involves acute medical emergencies, particularly when this requires intensive care support with pressor amines.[22] Such presentations can involve situations that may evolve into hypertensive crisis, multisystem failure, and shock preceded by or associated with cardiomyopathy, pulmonary edema, myocardial infarction, stroke, bowel ischemia, and acute kidney and liver injury. For the majority of cases, which are not caused by pheochromocytoma, there can be profound activation of the sympathoadrenal system that renders biochemical test interpretation difficult. When pheochromocytoma seems possible, it is appropriate to proceed directly to imaging studies. Biochemical testing is best carried out once the patient is stabilized.

PATHOLOGY

KEY POINTS

- In a minority of patients (10%–17%), the tumor may spread (metastasize) to other organs such as the lungs, bones, lymph nodes, or liver.
- There are no reliable pathologic features to predict whether metastases will or will not develop in the future.

Pheochromocytomas are well-circumscribed, encapsulated tumors that exhibit a typical endocrine pattern with chief nests (i.e., Zelballen pattern). The stroma surrounding and separating the nests is mainly composed of fibrovascular tissue. Sustentacular cells may be seen at the periphery of the cell nests. The tumors are characterized by positive chromogranin A staining and sustentacular cells that are positive for the S100 protein.[23,24] Pheochromocytoma is considered intraadrenal in origin if the cortex of the adrenal is found in close relationship with the pheochromocytoma on histopathological review.

Capsular and lymphovascular invasion, coarse nodularity, the presence of atypical nuclei, growth pattern, high proliferative index (Ki67), and the presence of comedonecrosis are often found in malignant pheochromocytoma (last three features having the highest predictive value), but it is impossible to distinguish malignant from benign tumors based on such histopathologic features.[24] Currently, there remains no well-accepted grading system. In the 2017 World Health Organization classification of endocrine tumors, the terminology of benign and malignant was removed, because all pheochromocytomas are now considered to have metastatic potential; thus, the term "malignant" has been replaced by the term "metastatic,"[25,26] now defined by the presence of metastatic lesions in bones and pathologically confirmed in lymph nodes, though lesions in liver or lungs are also useful.

Some patients may present with composite tumors, defined as a tumor that combines morphological features of pheochromocytoma with those of a developmentally related neurogenic tumor, including ganglioneuroma, ganglioneuroblastoma, neuroblastoma, or malignant peripheral sheath tumor.[24] Today, all pheochromocytomas and paragangliomas are covered by a new staging system: T1 = intraadrenal tumor = pheochromocytoma, T2 = extraadrenal tumor = sympathetic paraganglioma (not indicating metastases), T3 = tumor with invasion into surrounding tissue or lymph node metastasis, and T4 = tumor presenting with metastasis to bone or multiple other sites with or without lymph node involvement.[24]

GENETICS OF PHEOCHROMOCYTOMA

KEY POINTS

- Mutations of at least 20 different tumor susceptibility genes account for more than 70% of all pheochromocytomas and paragangliomas.
- An underlying mutation should be considered in all patients, regardless of family history or syndromic features.
- Certain clinical presentations of hereditary pheochromocytoma or paraganglioma depend on the underlying mutation.
- All patients with identified predisposing mutations or hereditary syndromes should receive periodic surveillance for the tumors to which they are susceptible (this also applies to tumors other than pheochromocytoma and paraganglioma).

Pheochromocytoma has the highest degree of heritability among all tumors; up to 40% of cases result from germline mutations.[4,27-29] In a similarly large proportion (30%), somatic mutations have been identified.[4,27,29] Mutations of at least 20 pheochromocytoma susceptibility genes have been identified to date, impacting ten of the most clinically relevant genes (Table 99.4). Pheochromocytoma separates into three main clinically relevant transcriptional cluster groups (pathways): the pseudohypoxia signaling (Cluster 1), kinase signaling (Cluster 2), and c/ Wnt signaling clusters.[4,27] The underlying mutation, as well as its close relationship to a particular cluster, relates to clinical presentation, including metastatic behavior, biochemical phenotype, cluster-specific imaging signature, and to some extent therapeutic response and nature of follow-up.[30-33] Currently, it is recommended that genetic testing should be considered in all patients,[1,34] and it is our recommendation that all patients should be seen by a genetic counselor. Genetic testing is particularly important in patients presenting at a young age, with a family history of pheochromocytoma or with extraadrenal, multiple, recurrent, and metastatic tumors.

Multiple Endocrine Neoplasia Syndromes

Multiple endocrine neoplasia 2 (MEN2) is an autosomal dominant syndrome (Sipple syndrome) affecting approximately one in 40,000 individuals and is characterized by medullary thyroid carcinoma, pheochromocytoma, and parathyroid hyperplasia/adenoma (Table 99.4).[35] The gene responsible for MEN2 is a protooncogene, *RET*, that is expressed in C cells in the thyroid gland and catecholamine-producing chromaffin cells in the adrenal gland. *RET* is located on chromosome 10q11.2 and encodes a receptor tyrosine kinase. As an oncogene, activation of *RET* leads to hyperplasia of target cells *in vivo*. Subsequent secondary events then lead to tumor formation.59 *RET* consists of 21 exons with six so-called "hot-spot exons" (exons 10, 11, 13, 14, 15, and 16) in which mutations are identified in 97% of patients with MEN2.

Pheochromocytomas in MEN 2 develop on a background of adrenomedullary hyperplasia and become manifest (e.g., biochemically or on imaging) in approximately 50% of patients. MEN2-associated pheochromocytomas are almost exclusively benign (with <5% reported to be metastatic) and localized to the adrenals. The peak age is approximately 40 years, but children as young as 10 years can be affected. Patients with MEN2-related pheochromocytoma often lack sustained hypertension or other catecholamine-related symptoms/signs (they occur only in ~50% of patients). MEN2-related pheochromocytomas are almost always intraadrenal, are often multifocal and bilateral (~30% at diagnosis, ~70% lifetime risk). MEN2-related pheochromocytomas produce both epinephrine and norepinephrine; "preferential" stimulation by epinephrine of β-adrenoceptors found on heart or vasculature causes palpitations and tachycardia, respectively.[36] Thus, the detection of MEN2-related pheochromocytoma is invariably based on elevations of plasma or urinary metanephrine, usually with additional elevations of normetanephrine. In addition, as with most epinephrine-producing pheochromocytomas, the hypertension is more likely to be paroxysmal than sustained.[37]

Patients with MEN2B also present with ganglioneuromatosis, multiple mucosal neuromas of eyelids, lips, and tongue, and connective tissue disorders that include marfanoid habitus, scoliosis, kyphosis, pectus excavatum, slipped femoral epiphysis, and pes cavus. This syndrome is caused by germline mutations in the *RET* protooncogene that affect the tyrosine kinase catalytic site of the protein. MEN2B-associated pheochromocytomas are associated with a higher risk of malignancy compared with MEN2A. The screening for MEN-related pheochromocytoma should start between ages of 10 and 16 years.[38]

Von Hippel–Lindau Syndrome

Another syndrome commonly associated with pheochromocytoma is von Hippel–Lindau (VHL), which is caused by mutations of a gene in chromosome 3 (3p25-26) that encodes the *VHL* tumor suppressor gene (Table 99.4).[39] Pheochromocytoma occurs in approximately 15%–20% of patients with *VHL* mutations. Deletions, truncations, or splice-site mutations are associated with low risk, in contrast to missense mutations, which are associated with a high risk of developing pheochromocytoma.[39,40] The mean age at diagnosis is 28 years.

The disease has been divided into two types based on the significant genotype–phenotype correlations observed. Type 1 includes mainly large deletions or disruptive mutations and expresses the full phenotype of vascular lesions of the retina (i.e., angiomas), cysts, or solid tumors in the brain or spinal cord (i.e., hemangioblastomas), pancreatic cysts, renal cell carcinoma (RCC), epididymal cystadenoma, and endolymphatic sac tumors, but low risk for pheochromocytoma. Type

TABLE 99.4 **Pheochromocytoma-Associated Mutations in Clinically Relevant Genes**

Syndrome	Gene	Penetrance	Bilateral/ Multifocal	Metastatic	PHEO or PGL	Biochemical Phenotype	Other Tumors and Important Findings
MEN2[*]	*RET*	50%	50%–80%	Rare	PHEO	EPI	Medullary thyroid cancer, hyperparathyroidism, marphanoid habitus, mucosal ganglioneuromas
VHL[#]	*VHL*	10%–30%	50%	5%–7%	PHEO	NE	Retinal angiomas, CNS hemangioblastomas, clear-cell renal carcinoma, pancreatic cysts, epididymal cystadenoma, endolymphatic sac tumors
NF-1[*]	*NF-1*	1%–2%	16%	5%–10%	PHEO	EPI	Café-au-lait spots, neurofibromas, medullary thyroid cancer, carcinoid tumors, peripheral nerve sheath tumors
PGL1[#]	*SDHD*	90% if paternally transmitted[†]	Inconsistent Reports	15%–20%	PGL; less commonly PHEO	NE and/or DA; some biochemically silent	Clear-cell renal carcinoma, GIST, pituitary adenoma, pulmonary chondroma
PGL2[#]	*SDHAF2/SDHD5*	100% if paternally transmitted	-	-	Head and neck PGL	Unknown	None known
PGL3[#]	*SDHC*	Inconsistent reports	Inconsistent reports	Rare	PGL, less commonly PHEO	NE and/or DA; some biochemically silent	Clear-cell renal carcinoma
PGL4[#]	*SDHB*	30%–50%	Rare	31%–71%	PGL; less commonly PHEO	NE and/or DA; some biochemically silent	Clear-cell renal carcinoma, GIST, pituitary adenoma, breast and thyroid cancer (?), neuroblastoma, pulmonary chondroma
PGL5[#]	*SDHA*	1%–13%	Inconsistent reports	30%–66%	PGL	NE and/or DA; some biochemically silent	Clear-cell renal carcinoma, GIST, pituitary adenoma
-[*]	*TMEM127*	Inconsistent reports	33%	<5%	PHEO	EPI	Clear-cell renal carcinoma
-	*MAX*	Inconsistent reports	67%	<25%	PHEO	Mixed EPI and NE	
[#]	*FH*	Approximately 1%	More reports needed, but usually high	More reports needed, but usually high	PHEO and PGL	NE	Cutaneous and uterine leiomyoma, type 2 papillary RCC
-[#]	*HIF2A (EPAS)*	None, somatic	100%	Over 40%	PHEO/PGL	NE	Duodenal Somatostatinoma, polycythemia
-	*HRAS*	Unknown	Low	Unknown	PHEO; less commonly PGL	EPI	More common in Chinese than Europeans[88]

[#]and * indicate that particularly these hereditary pheochromocytomas belong to cluster 1 or cluster 2, respectively.

CNS, Central nervous system; *GIST*, gastrointestinal stromal tumor; *EPI*, adrenergic; *DA*, dopaminergic; *NE*, noradrenergic; *PHEO*, pheochromocytoma; *PGL*, paraganglioma; *RET*, rearranged during transfection; *VHL*, von Hippel–Lindau; *NF-1*, neurofibromatosis 1; *SDHA–D*, succinate dehydrogenase subunits A, B, C, and D; *SDHAF2*, succinate dehydrogenase assembly factor 2; *TMEM127*, transmembrane protein 127; *MAX*, myc-associated factor X; *FH*, fumarate hydratase; *HIF2A* (*EPAS1*), hypoxia-inducible factor 2α (endothelial PAS domain–containing protein 1); *HRAS*, Harvey rat sarcoma virus oncogene/Hras protooncogene.

2, which is predominantly associated with *VHL* missense mutations, is defined by the occurrence of pheochromocytomas, either alone (type 2C) or in combination with hemangioblastomas (type 2A) or with hemangioblastomas and RCCs (type 2B) (Table 99.4).

Patients are often asymptomatic when they present with other aspects of this disease. This syndrome is variable in terms of the different organ systems involved and the extent of involvement from patient to patient and from family to family. Pheochromocytomas as part of the VHL syndrome have an exclusively noradrenergic phenotype, reflecting the production of norepinephrine.[41] These tumors are located mainly intraadrenally and are bilateral in approximately 50% of patients, with a less than 8% incidence of metastases. In addition, sympathetic paragangliomas are frequent (20%). Tumors are commonly found based on periodic annual screening or during searches for other tumors that are part of this syndrome. Therefore, when detected, these tumors are often small, and approximately 80% of pheochromocytomas found during screening are asymptomatic and are not associated with hypertension. In addition, they may evade detection by functional imaging. The chance of tumor recurrence or development of a second primary tumor resulting from the hereditary nature of VHL supports the need for lifelong surveillance. Screening for VHL-related pheochromocytoma should start around age 4 to 5 years and include measurement of blood pressure and plasma or urine metanephrines.[39,42]

Neurofibromatosis Type 1

Von Recklinghausen neurofibromatosis (NF) is divided into two types: NF-1 includes peripheral neurofibromas of peripheral nerves, whereas NF-2 has central nervous system schwannomas (Table 99.4). NF-1 is inherited in an autosomal dominant pattern. The association with pheochromocytoma is one between a relatively common disease and a rare disease. Current literature suggests that 7% of patients with NF-1 have pheochromocytoma, and approximately 5% of patients with pheochromocytoma have *NF-1* germline mutations.[43] Pheochromocytoma associated with NF-1 is caused by germ line mutations in chromosome 17 (17q11), where the *NF-1* gene encodes for the protein neurofibromin. Pheochromocytoma in patients with NF-1 is rarely seen in children; it usually occurs at a later age (around 50 years). Only 12% of all patients with NF-1 and pheochromocytoma are diagnosed with bilateral and multifocal pheochromocytomas, and less than 6% of patients have metastatic pheochromocytoma.

Previously, routine screening for pheochromocytoma in NF-1 patients was not recommended. Only those patients with hypertension or other symptoms/signs possibly related to catecholamine excess were considered for screening, reflecting the relatively low penetrance of pheochromocytoma in these patients. Continued adherence to this approach ignores improvements in biochemical testing that now allow easier and more efficient diagnosis of pheochromocytoma than formerly possible. A recent study by Kepenekian et al.[44] in 156 patients with NF-1 found that 10 out of 12 patients with pheochromocytoma (6.4% of total patients) were asymptomatic (six biochemically negative and six biochemically positive). Therefore, they recommended performing pheochromocytoma screening every 4 to 5 years in all patients with NF-1 after 40 years of age using both the measurement of metanephrines and anatomical imaging by either computed tomography (CT) or magnetic resonance imaging (MRI). Current guidelines suggest that screening for pheochromocytoma in patients with NF-1 be carried out once every 3 years starting at an age between 10 and 14 years.[45]

Succinate Dehydrogenase Gene Family

Germline mutations of the succinate dehydrogenase (*SDH*) gene family now represent a well-established and important cause of hereditary pheochromocytoma.[29] The *SDH* genes (*SDHA*, *SDHB*, *SDHC*, and *SDHD*) encode the four subunits of complex II of the mitochondrial electron transport chain,[46] which is essential for the generation of adenosine triphosphate (oxidative phosphorylation).

SDHB and *SDHD* mutations can lead to complete loss of SDH enzymatic activity, a phenomenon that has now been well linked to tumorigenesis through upregulation of hypoxic-angiogenetic–responsive genes.[47] The *SDHB*, *SDHC*, and *SDHD* genes are associated with the presence of familial and nonfamilial pheochromocytoma and sympathetic and parasympathetic paragangliomas (Table 99.4).[31,48,49] Frameshift, missense, and nonsense mutations, but also large deletions, were identified for the *SDH* gene family.

Studies have shown that approximately 4% to 12% of apparently sporadic pheochromocytomas and up to 50% of familial pheochromocytomas are associated with *SDH* mutations.[28,50,51] The *SDHB*, *SDHC*, and *SDHD* traits are inherited in an autosomal dominant fashion and give rise to familial paraganglioma syndromes 4, 3, and 1, respectively (see Table 99.4). For *SDHD* and *SDHAF2* genes, the disease almost always occurs only when the mutations are inherited from the father, which is consistent with maternal imprinting. Penetrance is incomplete, but for *SDHB* mutations ranges between 25% and 65% by age 80 and is higher in males than females.[52-55] *SDHB* mutations predispose mainly to sympathetic paragangliomas with a high metastatic potential.[56-59] *SDHD* mutations typically are associated with multifocal parasympathetic head and neck paragangliomas and less commonly with sypathetic paraganglioma and pheochromocytomas.[60] The incidence of metastatic pheochromocytoma/paraganglioma is less common in *SDHD* than *SDHB* mutations.[59] *SDHC* mutations are rare and associated with both sympathetic and parasympathetic paragangliomas and pheochromocytoma.[61] *SDH*-related pheochromocytomas and paragangliomas produce norepinephrine or both norepinephrine and dopamine and their metabolites.[62,63] Therefore, measurement of plasma levels of dopamine or its O-methylated metabolite methoxytyramine are important in *SDH*-related pheochromocytomas.[63]

More recently, *SDHA* gene defects were identified as a rare cause of abdominal, thoracic, and head and neck paragangliomas.[64] Also, mutations of SDH assembly factor 2 (SDHAF2), which is required for the assembly of mitochondrial complex II, were associated with familial head and neck paragangliomas, but not pheochromocytoma.[65]

Careful genetic counseling and genetic testing should be offered to all first-degree family members of patients with *SDH*-related pheochromocytoma, and subsequently it is recommended that periodic clinical, biochemical, and radiologic tumor screening be performed among mutation carriers. However, no evidence-based protocol has been used for tumor screening, and recommendations vary, from annual measurement of plasma or urinary metanephrines to performing a whole-body anatomic imaging study every 2 to 3 years starting between the ages of 5 and 10 years for *SDHB* and 10 to 15 years for *SDHD* mutations carriers.[5] Recent recommendations suggest that carriers of pathogenic SDH variants should be offered surveillance with annual biochemical screening and biannual whole-body MRI, together with clinical examination.[66] Surveillance should start 5 years before the earliest age of onset in the family, and thus only children eligible for surveillance should be offered presymptomatic genetic testing. The surveillance of children younger than 15 years needs to be individually designed. For patients with previous diagnosis of *SDH*-related pheochromocytoma, lifetime follow-up is necessary, with biochemical screening every 6 to 12 months (a shorter interval is usually recommended for *SDHB* mutation patients) and imaging every 1 to 3 years based on the initial diagnosis and surgery.

It should be also noted that pheochromocytoma, especially those related to *SDHx* mutations, also may occur as part of Carney's triad (i.e., gastric leiomyosarcoma, pulmonary chondroma, and paraganglioma). The syndrome is very rare, and only approximately 25% of patients manifest all three parts of the triad. It occurs sporadically, mainly in young women, and is clearly nonfamilial. More recently, a new syndrome called the Stratakis–Carney syndrome, or the "dyad of gastrointestinal stromal tumor and paraganglioma" was identified.[67] Another association with *SDH* mutations is occurrence of pituitary adenoma (so called 3P association: pheochromocytoma/paraganglioma/pituitary adenoma).[68]

Less Common Hereditary or Other Causes

The most recently reported hereditary forms of pheochromocytoma are related to four germline mutations that include transmembrane protein 127 (*TMEM127*),[69] myc-associated factor X (*MAX*),[70] fumarate hydratase (*FH*),[71] and dihydrolipoamide S-succinyltransferase (*DSLT*)[72] (Table 99.4). The *TMEM127* gene encodes a transmembrane protein that appears to be implicated in protein trafficking and/or the protein-recycling machinery. Genetic studies of pheochromocytoma patients carrying *TMEM127* mutations indicate a low prevalence of these variants (~2% of all cases negative for other susceptibility mutations).[73] The *TMEM127*-related phenotype mainly includes single benign pheochromocytomas of the adrenal glands. *MAX* behaves as a classic tumor suppressor gene and is a key member of the MYC-MAX-MXD1 network of basic helix-loop-helix leucine zipper transcription factors that regulate cell growth, proliferation, and stem cell development. The prevalence of germline *MAX* mutations among a large group of apparently sporadic cases of pheochromocytoma or paraganglioma was low (1.12%).[74] *MAX*-related pheochromocytomas are often multifocal, and the estimated prevalence of malignancy is 10%. FH is an enzyme in the Krebs cycle that converts fumarate to malate. Pheochromocytomas related to *FH* mutations present with a noradrenergic biochemical phenotype and, similar to other pseudohypoxia-related pheochromocytomas, are associated with higher rates of multiplicity and metastasis. DSLT is the part of the E2 subunit mitochondrial α-ketoglutarate dehydrogenase complex and facilitates conversion of α-ketoglutarate to succinyl CoA and carbon dioxide. The prevalence of germline *DLST* mutations among sporadic cases of pheochromocytomas is estimated to be around 1%.[72] Individuals with *DLST* mutations present with multiple pheochromocytomas.

Recent discoveries of somatic mutations related to pheochromocytoma include mutations in hypoxia-inducible factor 1α (*HIF2A* or *EPAS1*)[75] and Harvey-ras (*H-RAS*),[76] as outlined in the Table 99.4. *HIF2A* was found to be associated with a new syndrome of multiple pheochromocytomas and duodenal somatostatinomas associated with polycythemia (Pacak–Zhuang syndrome).[77] *HIF2A* somatic mutations were also reported in patients without polycythemia and occasionally may present as germline mutations. Somatic mutations of another two genes, alpha thalassemia/mental retardation syndrome X-linked (*ATRX*) and telomerase reverse transcriptase (*TERT*), are associated with more aggressive and metastatic behavior, but are not considered to be driver mutations.[3,78,79]

BIOCHEMICAL DIAGNOSIS OF PHEOCHROMOCYTOMA

KEY POINTS

- Measurements of plasma or urinary metanephrines provide the preferred biochemical tests for diagnosis of pheochromocytoma and paraganglioma.
- Appropriate preanalytical conditions and reference intervals are crucial for accurate interpretation of laboratory test results.
- Metanephrine test results within normal limits can exclude a diagnosis of pheochromocytoma or paraganglioma in virtually all symptomatic patients.

Although catecholamines are the principle hormones produced by pheochromocytoma, their measurement in urine or plasma is not reliable for detection of tumors. In contrast, because metanephrines are produced continuously from catecholamines within pheochromocytomas by a process independent of catecholamine secretion, these metabolites provide diagnostic advantages over the parent catecholamines.[80] Consequently, the 2014 Endocrine Society Clinical Practice Guideline on pheochromocytomas and paragangliomas recommended that testing for the tumors should include measurement of plasma or urinary metanephrines.[34] Since then, a multicenter prospective study involving mass spectrometry-based measurement of plasma free, urinary free, and urinary deconjugated metanephrines established that the diagnostic efficacy of plasma and urinary free metabolites are equally effective in symptomatic patients whereas the plasma test is superior to both urine tests in patients screened due to hereditary risk, an incidentaloma, or past history of the tumors.[81] The utility of measurements of methoxytyramine for diagnosis of dopamine-producing paragangliomas was further clarified to be restricted to plasma measurements.

Preanalytics and Analytics

False-negative results for measurements of metanephrines can occur but are rare, particularly for plasma measurements[81]; in contrast, there are numerous causes of false-positive results for both plasma and urine tests (Table 99.5). False negatives can occur with use of inappropriately high reference intervals, in small tumors or tumors that do not synthesize catecholamines, including some paragangliomas and particularly those confined to the head and neck. False negatives can also occur for paragangliomas that produce only dopamine when test panels do not include plasma methoxytyramine. For acid hydrolyzed urinary metabolites measured by liquid chromatography with electrochemical detection (LC-ECD), the presence of 3-methoxy-4-hydroxybenzylamine in dietary curry leaves can result in inaccurately low urinary outputs of all metabolites, and potentially false-negative results.[82]

False positives for plasma or urine tests are commonly associated with activation of the sympathoadrenal system or with the use of drugs, such as tricyclic antidepressants, that alter the disposition of norepinephrine (Table 99.5). For the plasma test, sampling blood in the seated position is a common cause of false-positive results.[83,84] Blood for this test should be collected with patients supine for at least 20 to 30 minutes before sampling.[34] If blood cannot be taken in the supine position, the next best test involves measurements of urinary free metanephrines either in a 24-hour collection or in a first morning urine sample.[81,85]

Immunoassays for metanephrines do not provide reliable accuracy for catecholamine-producing tumors.[86] Although methods employing LC-ECD remain in use for urine measurements, liquid chromatography with liquid chromatography tandem mass spectrometry (LC-MS/MS) is preferable for both plasma and urine. This is because LC-MS/MS is minimally impacted by analytical interferences compared with other methods. Nevertheless, analytical interferences, which are assay-specific and not covered here, are minor and highly variable causes of false-positive results compared with sympathoadrenal activation and pharmacophysiological causes of false-positive results.

Interpretative Considerations

Appropriately determined reference intervals for laboratory tests are essential for minimizing false-negative or false-positive results.[34] For plasma free metanephrines, upper cutoffs of reference intervals should be optimized for blood sampling in the supine position.[87] For plasma normetanephrine, age-specific upper cutoffs minimize false-positive results for older patients and false-negative results for younger patients. For measurements of metanephrines in urine, sex-specific reference intervals are appropriate. A related consideration is the use of creatinine for normalizations in spot urines, particularly important for children and patients in whom both sex and body size warrant consideration.

For most patients with pheochromocytoma, the extent and pattern of increases of multiple metabolites in a panel are usually sufficient to indicate a tumor. Assessing the posttest probability of disease should also take into account pretest prevalence according to clinical presentation or reason for testing.[16,81] Follow-up biochemical testing after screening is prudent for patients with milder increases (e.g., <2-fold above upper cutoffs) in solitary metabolites of test panels, where the posttest probability of pheochromocytoma remains low. Before follow-up testing is implemented, consideration should be directed toward sources of false-positive results (see Table 99.5).

Given the high diagnostic accuracy of today's biochemical tests, the need for follow-up pharmacologic procedures is negligible, and in particular provocative tests are obsolete. On the other hand, in some specific patients, suppression tests such as the clonidine suppression test may still be useful.[20] If plasma normetanephrine does not fall below 112 pg/mL (0.61 nmol/L) and by less than 40% 3 hours after administration of 0.3 mg/70 kg clonidine, a catecholamine-producing tumor is highly likely.

No tumoral catecholamine synthesis	FN+++	FN+++	FN+++	FN+++	FN+++	FN+++

*Interferences for urine are shown for deconjugated measurements after an acid-hydrolysis step, but except for MHBA are likely similar for urinary free measurements.

**Urine methoxytyramine is a poor marker of tumoral dopamine production.

[†] A wide array of foods (e.g., fruits, nuts, meats) can elevate methoxytyramine in plasma and deconjugated normetanephrine and methoxytyramine in urine.

[§] MHBA is an internal standard used in assays involving liquid chromatography with electrochemical detection, so only causes false-negative results for those assays.

FP, false positive; *FN*, false negative; +, weak influence; ++, mild influence; +++, strong influence; –, no influence; *?*, influence unknown; *na*, not applicable; *NE*, norepinephrine; *MAO*, monoamine oxidase; *MHBA*, 3-methoxy-4-hydroxybenzylamine; *UC*, upper cutoff.

Apart from indicating presence or absence of disease, biochemical test results may also provide information about tumor size and location, an underlying mutation, and the presence of metastases. Pheochromocytomas may produce exclusively norepinephrine or both norepinephrine and epinephrine. In contrast, sympathetic paragangliomas almost invariably produce only norepinephrine, with or without methoxytyramine. Although increases in metanephrine or methoxytyramine relative to normetanephrine can thus indicate respective adrenal versus extraadrenal tumor locations, there are ethnic differences that must be considered.[88] Differences in metabolite profiles more reliably relate to the nature of underlying mutations and can thereby be used to assist interpretation of pathogenicity after next-generation sequencing or interpret biochemical test results in patients with known mutations.[89] Finally, metastatic tumors are often characterized by increased dopamine production, best assessed by measurements of plasma methoxytyramine.[62]

Follow-Up Biochemical Testing

Follow-up biochemical testing during the several weeks after recovery from surgery is essential for documenting potential residual tumor mass or metastatic lesions.[90] Testing and interpretation of test results should be according to the nature of elevated metabolites in test panels before surgery. After return of normal test results, annual biochemical testing is recommended in all patients for at least 10 years after surgery. In patients with high risk of recurrence (paragangliomas, large or multifocal tumors, childhood presentation, or *SDHB* mutations), annual biochemical follow-up should be lifelong.[90] Such tests should ideally include plasma metabolites, including methoxytyramine.

LOCALIZATION OF PHEOCHROMOCYTOMA

KEY POINTS

- Anatomical imaging studies (i.e., computed tomography or magnetic resonance imaging) are first used to locate a pheochromocytoma or paraganglioma. Functional imaging studies, such as positron emission tomography, provide additional utility for confirmation.

Anatomic Imaging

In most institutions, CT of the abdomen provides the initial method of localizing pheochromocytoma; this imaging technique is easy, widely available, and relatively inexpensive (Table 99.6). A dedicated adrenal CT consists of three series: noncontrast, contrast-enhanced

TABLE 99.6 **Proposed Clinical Algorithm for Imaging Investigations in Pheochromocytoma**

	Anatomic Imaging	Functional Imaging
Pheochromocytoma (sporadic)	Adrenal CT or MRI	In selected cases: inconclusive result on anatomic imaging, size >5 cm, borderline elevation of metanephrines or uncertainty regarding their accuracy ^{18}F-FDOPA or ^{123}I-MIBG preferred as first choices ^{68}Ga-DOTA-SSAs as second choice
Hereditary pheochromocytoma (except *SDHx*): *NF1/RET/VHL/MAX*	Thoracoabdominopelvic CT or MRI	In selected cases: inconclusive results on anatomic imaging regarding bilaterality in *NF-1/RET*, in *VHL* (due to multifocality risk) and *MAX* (due to multifocality and malignancy risk) ^{18}F-FDOPA preferred ^{123}I-MIBG as second choice
Extraadrenal sympathetic and/or multifocal and/or metastatic and/or *SDHx* mutation	Thoracoabdominopelvic CT, craniocervical MRI, and temporal bone CT (for TP and JP)	^{68}Ga-DOTA-SSA preferred ^{18}F-FDG as second choice in *SDHx* ^{18}F-FDOPA as second choice in *VHL/HIF2A*
Head and neck paraganglioma (sporadic or unknown genetic background)	Craniocervical MRI (with DCE sequences), temporal bone CT (for TP and JP)	^{68}Ga-DOTA-SSA preferred ^{18}F-FDOPA as second choice

DCE, dynamic contrast enhanced; TP, tympanic paraganglioma; JP, jugular paraganglioma; CT, computed tomography; MRI, magnetic resonance imaging; ^{18}F-FDOPA, (^{18}F)-fluorodihydroxyphenylalanine; ^{123}I-MIBG, ^{123}I-metaiodobenzylguanidine; ^{68}Ga-DOTA-SSA, ^{68}Ga-DOTA–somatostatin analog; ^{18}F-FDG, (^{18}F)-fluorodeoxyglucose.

(at 60 seconds), and delayed images (at 15 minutes) of the abdomen. A contrast-enhanced CT is usually obtained in the presence of expected large and multiple lesions. Previously, there have been concerns regarding the administration of iodinated contrast to patients with pheochromocytoma. However, it is now established that modern contrast agents can be safely administered. Typically, pheochromocytomas have soft tissue attenuation with a spontaneous density measurement greater than 10 Hounsfield units and typically demonstrate avid enhancement.[91] Enhancement can be heterogeneous, or there may be no enhancement due to cystic or degenerated regions within the lesion. Sensitivity is approximately 95%, but specificity is approximately 50%. Sensitivity of CT for the detection of sympathetic paraganglioma is lower than that for pheochromocytoma. For head and neck paraganglioma, CT offers some advantages over MRI (e.g., better spatial resolution and fewer motion artifacts) and enables better evaluation of the temporal bone extension of jugular paraganglioma and tympanic paraganglioma (TP).

MRI is also a very reliable method of detection of pheochromocytoma (sensitivity is ~95%, and specificity is ~70%). MRI does not expose patients to ionizing radiation, which is critical in patient populations such as children, pregnant women, and those subject to lifelong imaging surveillance. Pheochromocytoma is classically described as appearing "light-bulb" bright on T2-weighted imaging. Pheochromocytoma is also usually hypointense on T1-weighted imaging with no signal loss on opposed-phase images and demonstrates avid contrast enhancement following gadolinium injection, similar to enhancement on CT. Many pheochromocytomas may show moderate or low T2-weighted signal intensity (in up to 30% of cases), an inhomogeneous appearance (especially if they are cystic and/or hemorrhagic). Diffusion-weighted MRI can be useful in depicting lymph node and liver metastases. MRI has been reported as superior to CT for the detection of extraadrenal tumors. For head and neck paraganglioma, MRI provides better soft-tissue contrast than CT and thus offers unique information for tumor delineation and grading according to recommended classifications. In this setting, there is a current trend to use four-dimensional time-resolved gadolinium magnetic resonance angiography; this typically shows an early and intense enhancement following gadolinium administration, with a rapid washout. *In vivo* magnetic resonance spectroscopy is also an emerging technique that can be performed in selected cases to assess succinate levels (e.g., *SDH*x mutations of unknown pathogenicity).[92,93]

Differential Diagnosis

Pheochromocytoma can be mistaken for an adrenal cyst, a hematoma, an atypical adenoma, or an adrenocortical carcinoma. The imaging differential for retroperitoneal masses includes primary and secondary malignancies such as lymphoma, primary retroperitoneal sarcoma, malignant nerve sheath tumors, Castleman disease, and nodal metastases from primary malignancies. Differential diagnoses of head and neck paraganglioma are also numerous and include nerve sheath tumors (schwannoma and neurofibroma), lymph node metastasis, miscellaneous lesions, middle ear adenoma (for TP), and other rare neoplasms.

Functional Imaging

Nuclear imaging offers several advantages over anatomic imaging, such as its higher specificity conferred by the use of very specific tracers and the high visual contrast between tumor and healthy tissue, which enables the detection of tumors that could potentially be missed by anatomic imaging. Beyond its localization value, the diversity of radiopharmaceuticals provides unique opportunities for enhanced characterization of these tumors at the molecular level (e.g., catecholamine synthesis, transporter expression, somatostatin receptor expression, glucose metabolism), mirroring histological classification on a whole-body, *in vivo*, scale. These imaging phenotypes also often reflect the diverse genetic landscape of pheochromocytoma (Table 99.6). It should be noted that pheochromocytoma related to *SDH* mutations may be functionally dedifferentiated, leading to an inability to accumulate pheochromocytoma-specific radiopharmaceuticals.

Metaiodobenzylguanidine Scintigraphy

Metaiodobenzylguanidine (MIBG) is an iodinated analog of guanidine, with some structural similarities to norepinephrine. It is taken up by cells via the norepinephrine transporter and stored within the neurosecretory granules via vesicular monoamine transporters 1 and 2.[94] Many drugs modify the uptake and storage of MIBG, such as opioids, tricyclic antidepressants, antipsychotics, and some antihypertensive agents such as labetalol. ^{123}I-MIBG scintigraphy is strongly preferred over ^{131}I-MIBG scintigraphy for various reasons (e.g., better image quality, lower radiation burden, shorter need of thyroid blockade). Thyroid blockade should be performed 1 hour before ^{123}I-MIBG injection. Discontinuation of drugs interfering with MIBG uptake and retention is also required. ^{123}I-MIBG scans are usually obtained 24 hours after tracer injection and consist of planar and a single photon emission computed tomography (SPECT)/CT images. Normal uptake of ^{123}I-MIBG in the adrenals is observed up to 80% of the time and should be considered physiological if it is mild and symmetrical and if the adrenals are not enlarged on CT images.

Pheochromocytomas and sympathetic paragangliomas are detected by intense tumor uptake on ^{123}I-MIBG scan (sensitivity 83%–100%, specificity approaching 100%). Sensitivity is decreased in infracentimeter tumors (due to limited spatial resolution), *SDH*-related and metastatic pheochromocytoma, and head and neck paraganglioma. Despite the lower sensitivity for detecting metastases, a very important advantage of using ^{123}I-MIBG scintigraphy in the setting of metastatic disease is the fact that it can identify patients who are likely to benefit from targeted radionuclide therapy with low- or high-specific-activity ^{131}I-MIBG. In other clinical scenarios, positron emission tomography (PET), if available, is preferred for comprehensive localization of the disease, especially in more complex scenarios such as hereditary and/or metastatic pheochromocytoma.

Positron Emission Tomography

The advantages of PET are that it can be done within minutes or hours after injection of short-lived positron-emitting agents, radiation exposure is low, and sensitivity and spatial resolution is superior to SPECT. Two sympathoneuronal PET imaging agents that target norepinephrine transporter, (18F)-fluorodopamine and 11C-hydroxyephedrine (11C-HED), have been evaluated but are unfortunately not available at most centers and are not approved for use. Moreover, the short half-life of ^{11}C-HED is a major drawback for its routine clinical use.

The target of (^{18}F)-fluorodihydroxyphenylalanine (DOPA) is the L-type amino acid transporters (mainly LAT1 and LAT2) involved in the uptake of amine precursors. DOPA PET is very specific and can also visualize head and neck paraganliomas. Only a few anecdotal case reports of DOPA uptake in nonneuroendocrine malignancies have been reported, such as solid pseudopapillary tumor of the pancreas, thyroid neoplasm of follicular origin (oncocytoma), squamous cell carcinoma (cervix, epiglottis), poorly differentiated adenocarcinoma, and melanoma. Another advantage of using 18F-F DOPA instead of other radiopharmaceuticals for PET/CT is its limited uptake by normal adrenal glands, which allows detection of small pheochromocytomas due to *RET* or *MAX* mutations.[95] A metaanalysis including 11 studies involving 275 patients with pheochromocytomas and paragangliomas showed that the pooled sensitivity and specificity in a lesion-based analysis of DOPA PET/CT were 79% (95% confidence interval [CI]: 76%–81%) and 95% (95% CI: 84%–99%), respectively.[96]

In cases of sporadic pheochromocytoma, DOPA scanning has a sensitivity of nearly 100% and is also very sensitive for detection of pheochromocytoma related to *VHL*, *EPAS1* (*HIF2A*), and *FH* mutations.[97] In contrast, decreased sensitivity is observed for *SDH*-related pheochromocytoma of sympathetic origin, including metastatic cases. In this setting, (^{18}F)-fluorodeoxyglucose (FDG) PET was found to offer improved performance over DOPA PET and ^{123}I-MIBG.[98] The increased glucose metabolism, which characterizes *SDH*-related pheochromocytoma, has been attributed to metabolic reprogramming due to Krebs cycle blockade (pseudohypoxia)[99] and activation of the surrounding stromal tissue.[100] ^{1}FDG PET has however been surpassed by ^{68}Ga-DOTA–somatostatin analogs (SSAs).[101]

In a systematic review and metaanalysis, the pooled detection rate of pheochromocytoma and paraganglioma using ^{68}Ga-DOTA-SSA PET/CT was 93% (95% CI: 91%–95%), which was significantly higher than that of DOPA PET/CT (80% [95% CI: 69%–88%]), FDG PET/CT (74% [95% CI: 46%–91%]), and $^{123/131}$I-MIBG scintigraphy (38% [95% CI: 20%–59%], $P < 0.001$ for all) (Fig. 99.2).[102] This metaanalysis was, however, hampered by the mix of pheochromocytomas of various origin and genotypes. Head-to-head comparison between ^{68}Ga-DOTA-SSAs and DOPA PET/CT has been performed in only seven studies. Overall, ^{68}Ga-DOTA-SSAs is the most sensitive tracer for head and neck paragangliomas and *SDH*-related and metastatic pheochromocytomas and sympathetic paragangliomas, regardless of their genetic background. Physicians should be aware of possible false-positive findings, including uncinate process, duodenal heterotopic pancreatic tissue, accessory spleen (pancreatic tail), splenosis, pancreatic serous cystadenoma, bone hemangioma (vertebral), enchondroma, fibrous dysplasia, active chronic inflammation (e.g., sarcoidosis, tuberculosis, Hashimoto thyroiditis), and other somatostatin receptor-expressing tumors (e.g., meningioma, breast cancer, lymphoma, thyroid neoplasms). In hereditary syndromes (e.g., VHL), uptake can be related to another primary neuroendocrine tumors or other malignancies (e.g., central nervous system hemangioblastoma).

In summary, imaging of patients with confirmed or suspected pheochromocytoma is important in every step of their management. Although CT and MRI have excellent sensitivity, these anatomic imaging approaches may lack the specificity required to identify a mass unequivocally as a pheochromocytoma. The recent excellent results obtained with ^{68}Ga-DOTA-SSAs has simplified the diagnostic approach to pheochromocytoma (Table 99.6) and can also assess their somatostatin receptor expression for peptide receptor radiotherapy.[103]

MANAGEMENT OF PHEOCHROMOCYTOMA

KEY POINTS

- Prompt surgical resection via minimally invasive surgery provides optimal treatment of pheochromocytoma in nearly all patients.
- Surgical intervention in patients with a biochemically positive pheochromocytoma or paraganglioma should be performed after preoperative blockade of the actions of catecholamines (α-adrenoceptor blocker for 7–14 days prior to surgery).
- Postoperative management includes follow-up biochemical testing to confirm success of surgical intervention, with continual follow-up to screen for recurrent or metastatic disease.

An individualized management approach in patients with pheochromocytoma may be expected to assure best outcomes. The optimal therapy for a pheochromocytoma is prompt surgical removal of the tumor; this is because an unresected tumor represents a time bomb waiting to explode with a potentially lethal cardiovascular crisis.[36] In today's experienced teams, most retroperitoneal tumors can be resected safely with a mortality rate approaching zero due to the many improvements in current clinical practice (experienced and coordinated team, preoperative preparation, laparoscopic approach, new anesthetic drugs and monitoring devices).[104,105]

Minimally invasive surgery by laparoscopic adrenalectomy is the first choice technique in all patients with pheochromocytoma, as it is associated with lower operative blood loss and shorter hospital stay than open adrenalectomy.[106,107] Robotic adrenalectomy and a single-port approach are evolving, but so far, the benefits over laparoscopic adrenalectomy have not been established.[108]

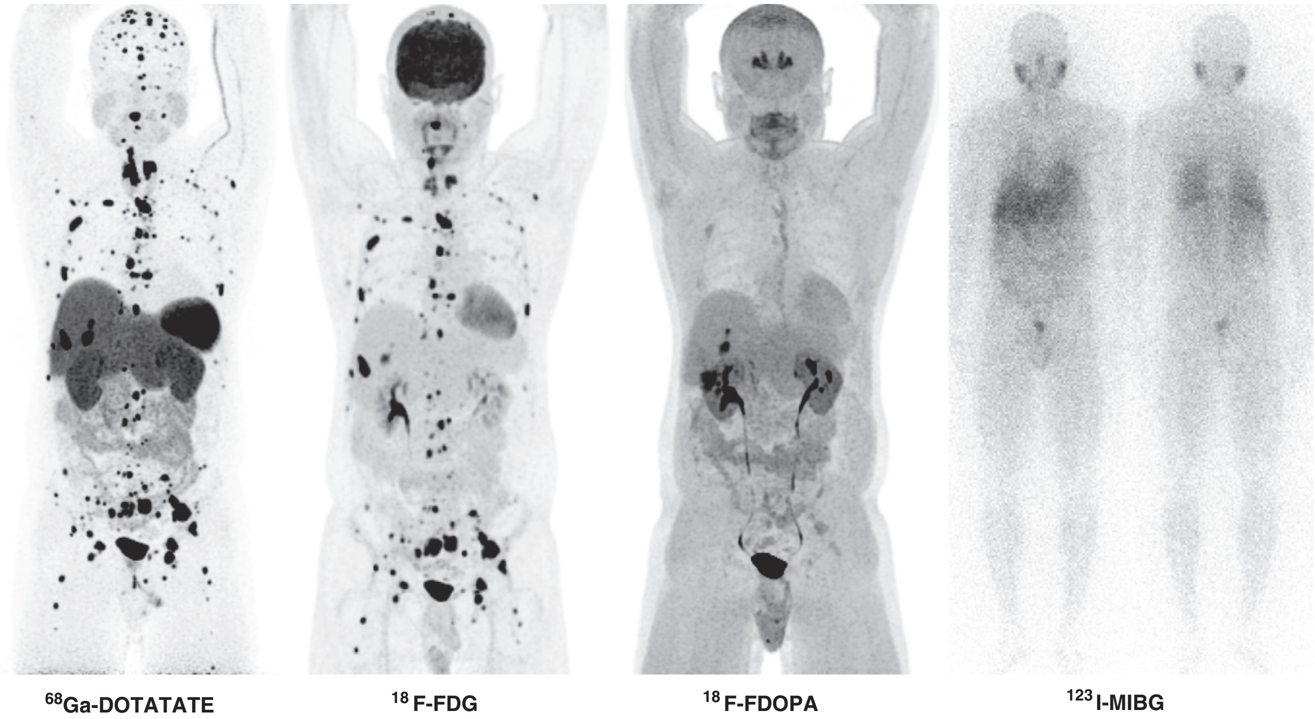

Figure 99.2 **Metastatic *SDHB*-related paraganglioma.** A 41-year-old male with *SDHB*-related metastatic paraganglioma in multiple bones, liver, and pelvic nodes showing variable tumor localization on multimodality molecular imaging. ^{68}Ga-DOTATATE positron emission tomography (PET)/computed tomography (CT) shows the highest number of lesions of any of the imaging modalities, followed by (^{18}F)-fluorodeoxyglucose PET/CT. (^{18}F)-fluorodihydroxyphenylalanine PET/CT and ^{123}I-metaiodobenzylguanidine scintigraphy are suboptimal due to functional dedifferentiation. This imaging phenotype is typical of metastatic *SDHx*-related pheochromocytoma and paraganglioma.

Head and neck paragangliomas often exhibit indolent behavior and rarely secrete catecholamines. Although complete surgical resection is the only curative treatment for these tumors, it may not be advised due to their size and specific anatomical location. Additionally, lower cranial nerve injury represents a major risk in surgical resection. Surgery should therefore be considered in Shamblin class I and II carotid body and most tympanic paragangliomas. *SDHB*- and *SDHD*-related carotid body paragangliomas should be surgically removed when they reach size of 1.5 or 2 cm, respectively. In other cases (e.g., vagal or jugular paragangliomas), observation or various forms of therapeutic radiation and, in some patients with rapidly growing tumors, chemotherapy should be considered as first choices.[60,109]

Medical Therapy and Preparation for Surgery

The main goal of preoperative management of a pheochromocytoma patient is 3-fold: 1) to normalize blood pressure, heart rate, and function of other organs; 2) to restore volume depletion; and 3) to prevent a surgery-induced catecholamine storm, with its consequences on the cardiovascular system and metabolism.[17,18] Therefore, when preoperative adrenoceptor blockade is initiated, the finally used drug doses are usually much higher, more than one drug is often necessary, and targets for cardiovascular indices are much more strict than they would be if no operation were performed (Table 99.7). The minimal duration of pretreatment is usually 7 to 14 days. Panels of experts either under the US Endocrine Society or the European Society of Hypertension recommended that all patients with a biochemically positive pheochromocytoma should receive appropriate preoperative medical management to block the effects of released catecholamines.[1,34] The recommendations on preoperative preparation with α-adrenoceptor blockade are based on optimal care of a pheochromocytoma patient, not only during surgery but also before surgery, when cardiovascular emergency and crisis may occur.

Despite wide-ranging practices, international differences in available or approved therapies, and a scarcity of evidence-based studies comparing different therapies, α-adrenoceptor blockers are the therapy of choice (Table 99.7). Other antihypertensives such as calcium channel blockers may be occasionally used in situations where there is only very mild elevations of blood pressure. For tachyarrhythmias, β-adrenoceptors or the calcium channel blocker verapamil are recommended. Correct use of these drugs, as well as improved surgical and anesthesiologic approaches, advances in medical imaging, and overall perioperative care, resulted in a significant drop in perioperative mortality, which is currently approximately 0% to 3 %.[110]

Maintenance of adequate blood pressure control for at least 1 to 2 weeks before the operation is an important aspect of management. Although no specific consensus on blood pressure and heart rate targets has been established, a seated blood pressure target of less than 130/80 mm Hg and upright systolic blood pressure of greater than 90 mm Hg has been proposed (Table 99.7).[34] Suggested targets for heart rate are 60 to 70 bpm in a seated and 70 to 80 bpm for an upright position, respectively.

Currently, nonselective and selective α-adrenoceptor blockers are available for treatment of patients with biochemically positive pheochromocytoma (Table 99.7).[17,18] Phenoxybenzamine is a noncompetitive nonselective α-adrenoceptor blocker commonly used for preoperative blockade. Phenoxybenzamine has a long-lasting effect that diminishes only after *de novo* α-adrenoceptor synthesis. The initial low dose of long-acting phenoxybenzamine of 10 mg twice daily

TABLE 99.7 Proposed Algorithm for the Preoperative Treatment of Patients With Pheochromocytoma

Start α-adrenoceptor blocker at least 7–14 days before surgery
Oral salt and fluid loading (e.g., keep regular salt diet, may use NaCl tablets/250 mmol = 15 g/one to three tablets a day)
Gradually increase α-adrenoceptor blocker until hemodynamic goals* are met (e.g., until maximum dose of phenoxybenzamine 30–40 mg three times daily or doxazosin 12–15 mg twice daily)
Add β-adrenoceptor blocker after at least 2–4 days of α-adrenoceptor blocker, when significant tachycardia or a catecholamine-induced arrhythmia occurs (e.g., atenolol 12.5–25 mg once or twice daily, metoprolol 25–50 mg once, twice, or three times daily)
Gradually increase β-adrenoceptor blocker until hemodynamic goals* are met
Add calcium-channel antagonist when hemodynamic goals* are not met despite maximum α-adrenoreceptor blockade (e.g., nifedipine or amlodipine)
Administer a saline infusion (e.g., 2 L NaCL 0.9% in 24 hours) 12–24 h before surgery

*Hemodynamic goals: supine systolic/diastolic blood pressure <130/80 mm Hg, systolic blood pressure in the upright position between 90 and 110 mm Hg, heart rate <80 beats per minute in the supine position and <100 beats per minute while standing.
Adapted from Berends et al.[18]

is to prevent early orthostatic hypotension; the dose is increased until clinical manifestations are controlled or intolerable side effects appear. For most patients, a total daily dose of 1 mg/kg is sufficient. Nevertheless, some patients may require much larger doses. Other useful α-adrenoceptor blocking agents are prazosin, terazosin, and the more commonly used doxazosin; all are more readily available and less expensive than phenoxybenzamine. All three drugs are competitive and short-acting α1-adrenoceptor blockers; all three may have the potential for severe postural hypotension immediately after the first dose (especially prazosin), which therefore should be administered just as the patient is ready to go to bed. Thereafter, the dose can be increased as needed.

The efficacy of phenoxybenzamine versus doxazosin on hemodynamic instability during surgery has been recently evaluated in PRESCRIPT, the first randomized controlled trial on presurgical treatment of patients with pheochromocytoma and paraganglioma.[110] It was concluded that although phenoxybenzamine was more effective in preventing intraoperative hemodynamic instability than doxazosin, there was no difference in clinical outcome between drugs. Another study showed that the non-selective α-adrenoceptor blocker, phenoxybenzamine, produced a more significant antihypertensive effect than selective α-adrenoceptor blockade in patients undergoing adrenalectomy.[111] However, no significant difference in intraoperative hemodynamic instability, postoperative recovery, or postoperative complications was observed between groups. Some retrospective studies, however, found that phenoxybenzamine may cause more pronounced postoperative hypotension than selective α-adrenoceptor blockade.[112]

It should be emphasized that, together with α-adrenoceptor blockers, patients are encouraged to consume a normal or high-salt diet and engage in high fluid intake to restore diminished blood volume to normal. This ameliorates the severity of postural hypotension due to α-adrenoceptor blockade.

Labetalol is another drug that has both α- and β-adrenoceptor blocking activity, and has been used in patients with pheochromocytoma, usually at a dosage of 200 to 600 mg twice daily. However, due to its stronger blocking effect on β- than α-adrenoceptors, it can only be used in those who are on another α-adrenoceptor blocker to avoid unopposed α-adrenoceptor-induced vasoconstriction due to loss of β-adrenoceptor-mediated vasodilatation, potentially resulting in a hypertensive crisis.

β-adrenoceptor blockers are needed only when significant tachycardia or a catecholamine-induced arrhythmia occurs (Table 99.7).[36] β-adrenoceptor blockers such as atenolol or metoprolol can be used. β-adrenoceptor blockers, however, should never be used before α-adrenoceptor blockers are administered, because unopposed stimulation of α-adrenoceptors due to loss of β-adrenoceptor-mediated vasodilatation may elicit a serious and life-threatening elevation of blood pressure.[36]

Metyrosine is a drug that can be also used in the treatment of patients with pheochromocytoma, but only as an add-on after appropriate adrenoceptor blockade has been initiated. The drug competitively inhibits tyrosine hydroxylase, the rate-limiting step in catecholamine biosynthesis depleting catecholamine stores. Thus, it facilitates blood pressure control both before and during surgery, especially during the induction of anesthesia and surgical manipulation of large tumors with largely elevated catecholamine/metanephrine levels. Treatment is started at a dosage of 250 mg orally every 6 to 12 hours; thereafter, the dose is increased by 250 to 500 mg every 2 to 3 days. Inhibition of catecholamine synthesis in the brain may often cause sedation and depression, as well as extrapyramidal signs (e.g., Parkinsonism) in older patients.

Hypertensive crises that can manifest as severe headache, visual disturbances, or cerebrovascular accidents can be appropriately treated with an intravenous bolus of 5 mg phentolamine. Phentolamine has a very short half-life; therefore, if necessary, the same dose can be repeated every 2 minutes until hypertension is adequately controlled, or phentolamine can be administered as a continuous infusion (100 mg of phentolamine in 500 mL of 5% dextrose in water). It is contraindicated in patients with coronary artery disease or heart failure, as it can cause severe vasodilation and reflex tachycardia. A continuous intravenous infusion of sodium nitroprusside, urapidil (α_1-adrenoceptor blocker), or calcium channel blockers such as nicardipine, diltiazem, or clevidipine or hydralazine as vasodilators can be used to control hypertensive crisis, as recently extensively reviewed.[36] Attention should also be paid to the possibility that some drugs (e.g., tricyclic antidepressants, metoclopramide, naloxone) can cause hypertensive crisis in patients with pheochromocytoma (Table 99.3). Severe tachyarrhythmia can be treated by intravenous esmolol or metoprolol (β_1-adrenoceptor blocker). A proposed algorithm for preoperative treatment is shown in Table 99.7.

Postoperative Management

Volume replacement is the treatment of choice if hypotension should occur during surgery (i.e., after the tumor is removed) or in the postoperative period.[113] Control of postoperative hypotension is even more imperative if both metyrosine and phenoxybenzamine are used preoperatively because the former inhibits catecholamine synthesis by both the tumor and the sympathetic nervous system, whereas the latter blocks the action of any catecholamines that are synthesized. In this situation, the vascular bed is effectively paralyzed, resulting in a vasodilated state. Therefore, the best way to control blood pressure is using adequate volume replacement. The volume of fluid required is often large (0.5–1.5 times the patient's total blood volume) during the first 24 to 48 hours after removal of the tumor. The amount of fluid replacement needed is readily determined by observation of blood pressure, heart rate, central venous pressure, and urinary output. If hypotension persists despite adequate volume replacement, infusion of norepinephrine or other pressor agents such as vasopressin may be warranted.[113]

Postoperative hypertension may indicate that some tumor tissue was not resected. However, during the first 24 hours after surgery, hypertension is most likely attributed to pain, volume overload, or autonomic instability; these are all readily treated symptomatically. If hypertension persists in a patient even after he or she has returned to dry weight, the coexistence of essential hypertension is still the most likely diagnosis. Any attempt to collect specimens for biochemical evidence of a residual tumor should be delayed at least 3 to 5 days postsurgery to ensure that the large increases in both plasma and urinary catecholamines due to sympathetic activation by surgery have dissipated. Usually, 3 to 6 weeks after surgery, every patient should undergo repeated measurement of plasma metanephrines to detect any residual tumor. It should be noted that at least 25% of patients remain hypertensive, but this is usually easily controlled with medication. Some patients may also present with postoperative hypoglycemia, usually during the first 24 hours due to persisting inhibitory effect of high catecholamines on insulin secretion. A hypoglycemic event needs to be treated with intravenous administration of glucose.[113] Postoperative management of patients with pheochromocytoma has been recently extensively reviewed and summarized by Mamilla et al.[113]

SPECIAL PRESENTATIONS AND THERAPEUTIC PROBLEMS

Multifocal and Metastatic Pheochromocytoma/Paraganglioma

KEY POINTS

- There are currently no effective cures for metastatic pheochromocytoma or paraganglioma. However, palliative relief may be achieved through therapeutic procedures that should be considered according to presentation (e.g., surgical debulking, 131I-metaiodobenzylguanidine radiotherapy, ^{177}Lu-DOTATATE radiotherapy, or chemotherapy).

Approximately 10% to 17% of the patients with a pheochromocytoma have metastatic disease, with prevalence highly dependent on the underling gene mutation. In approximately 20% of cases, metastases are discovered synchronously with initial diagnosis of a primary tumor. In other cases, metastases may develop metachronously after several years or even decades after diagnosis and intended curative treatment of primary tumors. The most frequent metastatic locations are lymph nodes (80%), bones (72%), liver (50%), and lungs (50%).[56,114,115] In rare cases, metastases to the brain, breasts, skin, and ovaries have been described.

A larger than 5 cm diameter, an extraadrenal location of the primary tumor, and high plasma concentrations of methoxytyramine are established determinants of metastatic risk.[57,58] The most prominent molecular marker to predict a malignant course is the presence of a germline *SDHB* mutation.[57,58,116]

The natural course of metastatic pheochromocytoma is highly heterogeneous among patients. The overall 5-year survival rate lies between 34% and 85%.[56,117] Mortality, progression-free survival, and clinical outcome are difficult to predict on an individual basis. Patients may have (very) indolent disease, despite the presence of extensive distant metastases, especially when confined to the skeleton. These patients may have an excellent quality of life and may need little or no therapeutic intervention for a prolonged period of time. In a French series, half of therapy-naive patients with metastatic pheochromocytoma achieved stable disease at 1 year follow-up.[118] On the other hand, some patients suffer from aggressive disease that requires systemic therapy. Several factors have been linked to decreased survival as outlined above. This includes the presence of a germline mutation in *SDHB* with a prevalence of 30% in patients with metastatic pheochromocytoma and up to 90% if the tumor originates from an extraadrenal location.[116]

Currently, there are no formal guidelines for treatment of metastatic pheochromocytoma, though application of the most common treatment modalities may follow certain considerations related to positivity on ^{123}I-MIBG or ^{68}Ga-DOTATATE scans (radionuclide therapy), rapid growth (chemotherapy), and clinically relevant compression (e.g., spinal cord) (surgery). Treatment should be tailored to the individual patient, with appropriate management that requires a multidisciplinary approach, involving specialists in endocrinology, oncology, surgery, radiotherapy, interventional radiology, pathology, and others. The goals of treatment are to prevent and manage catecholamine-related adverse events, reduce tumor size, prevent tumor progression, and palliate symptoms related to tumor burden.

In patients with limited metastatic disease, such as lymph node metastases, extended surgical resection can be considered, but rarely with a curative outcome. Even in the presence of incurable disease, resection (or debulking) of the primary tumor may be of benefit for survival. Other local therapies that can be applied for local symptom relief include external beam irradiation, radiofrequency ablation, tumor embolization, cryotherapy, and percutaneous microwave coagulation. Patients with epidural cord compression may benefit from spine surgery, external beam irradiation, or a combination of both. Stable compression fractures can be safely treated with percutaneous cement injection. Spinal instability can only be treated with surgery. Prior to these interventions patients should receive adrenoceptor blockers, with the only exceptions being those in whom it is clear that disease does not involve production of catecholamines. Such blockade is also essential to control symptoms of catecholamine excess and minimize risk of catecholamine crisis. In some cases, metyrosine might be required to block catecholamine synthesis.

Apart from cardiovascular manifestations, patients with metastatic pheochromocytoma can suffer from severe constipation or even pseudoobstruction due to inhibitory actions of catecholamines, in particular norepinephrine, on bowel motility. Such presentations can benefit from vigorous additional treatment with laxatives.

Targeted radiotherapy with ^{131}I-MIBG can be considered in patients with MIBG-positive metastatic lesions on diagnostic scanning. Both high-dose regimens and fractionated low-dose regimens can be effective in achieving a therapeutic response. A metaanalysis on the effectiveness of different regimens of ^{131}I-MIBG radiotherapy showed a complete response in 3%, a partial response in 27%, and stable disease in 52% of the patients.[119] Biochemical responses were as follows: 11% complete response, 40% partial response, and 21% stable disease. ^{131}I-MIBG treatment is generally well-tolerated, although high-dose regimens may cause bone marrow toxicity. More recently, positive effects have also been reported for ultratrace iobenguane, a high-specific-activity formulation of ^{131}I-MIBG that is US Food and Drug Administration-approved in the United States.[120]

A potentially more effective treatment than ^{131}I-MIBG radiotherapy involves peptide receptor radionuclide therapy (PRRT) with radiolabeled somatostatin analogs, which can be considered in patients with metastases that are positive on somatostatin receptor-targeted PET scanning. Prospective evaluations of this treatment modality are underway, but according to a systematic review and metaanalysis, treatment with PRRT achieved an objective response rate of 25% and a disease control rate of 84%.[121] Clinical and biochemical responses were seen in 61% and 64% of patients, respectively. Similar tumor response rates were noted for ^{90}Y-yttrium– and ^{177}Lu-lutetium-based PRRT regimens. Treatment-related adverse effects such a bone marrow toxicity and nephrotoxicity appear to be limited, especially with ^{177}Lu-DOTA-SSA.

Different chemotherapeutic agents have been used for metastatic pheochromocytoma/paraganglioma, including cyclophosphamide, doxorubicin, vincristine, dacarbazine, temozolomide, 5-fluorouracil, methotrexate, ifosfamide, streptozotocin, and platinum compounds.[122] The best-studied protocol, although in retrospective studies only, is the combination of cyclophosphamide, vincristine, and dacarbazine, usually administered in 21-day cycles. Complete and partial radiological response rates were 11% and 44%, respectively.[123] The median duration of response was 20 months. There was no difference in overall survival between patients whose tumors objectively shrank and those with stable or progressive disease. However, this combination chemotherapy can facilitate control of blood pressure as well as symptoms.[124] On the other hand, quality of life may be negatively impacted by side effects. Patients who are most likely to benefit from chemotherapy are those with rapidly progressive disease and tumor-related symptoms that cannot be easily controlled by supportive therapies. As an oral alternative, temozolomide has been successfully applied in some patients with metastatic pheochromocytoma due to *SDHB* mutations.[32] The role of chemotherapy in a (neo)adjuvant setting of pheochromocytoma remains to be determined.

In a subset of patients, antiangiogenetic treatment with tyrosine kinase inhibitors such as sunitinib may result in a partial response, disease stabilization, and improved blood pressure control.[125] Prospective clinical trials are ongoing.

Pediatric Pheochromocytoma

KEY POINTS

- The prevalence of hereditary cases is higher in children than in adults. Mutations associated with higher prevalences of extraadrenal, multifocal, metastatic, and recurrent pheochromocytomas are particularly higher in children than in adults.

Presentations of pheochromocytoma in children deserve special consideration, particularly due to the much higher prevalence of hereditary cases than in adults, especially cluster 1 mutations that lead to activated pseudohypoxic pathways.[126] More specifically, tumors due to cluster 1 mutations (*VHL*, *SDHB/D*) are twice as prevalent among children than adults, whereas the prevalence of cluster 2 mutations involving *RET*, *NF1*, *TMEM127*, and *MAX* is 3-fold lower in children than in adults. Due to the above differences, children show considerably higher prevalences of extraadrenal, multifocal, metastatic, and recurrent pheochromocytomas than adults. The genes most commonly reported to harbor mutations as the cause of childhood pheochromocytoma include, in decreasing prevalence, *SDHB, VHL,* and *SDHD* and, at a much lower prevalence, *RET*.[127-129]

Considering the high prevalence of underlying germline mutations in children, even in apparently sporadic cases, involvement of a genetic counselor is essential in all cases of pediatric pheochromocytoma. Importantly, most children who present with metastatic pheochromocytoma harbor *SDHB* mutations (metastases, which often develop within 7 years after the initial diagnosis of a primary tumor, are the most common cause of death).[130]

Because of the early age of development of hereditary pheochromocytoma and associated tumors including well-defined syndromes (e.g., retinal hemangioblastoma in VHL syndrome, medullary thyroid cancer in MEN2), it is recommended that screening for mutations in relatives of identified carriers begin in early childhood, as outlined earlier. It should be also noted that several somatic or *de novo* mutations of pheochromocytoma susceptibility genes (*HIF2A*, *NF1*, *VHL*) have been reported in pediatric pheochromocytoma.[77] Thus, physicians should be aware of the fact that some pediatric patients may not present with any positive family history.

Pheochromocytomas are the most common endocrine tumors in children, but only account for 10% to 14% of all pheochromocytomas, with a detected incidence of less than 2 per million per year.[131] Nevertheless, this prevalence is likely a gross underestimate, because many pheochromocytomas that develop in childhood are likely not diagnosed until early adulthood.[126] This can be appreciated from considerations of the generally slow-growing nature of pheochromocytoma; with an average doubling time of 2 years,[132] it can be calculated that it would take 12 years for a 1-cm-diameter tumor (0.52 cubic cm volume) to reach a diameter of 4 cm and a volume of 33 cubic cm. Because the peak age at diagnosis of cluster 1 pheochromocytomas is 30 years,[133] a substantial proportion of such tumors must actually first develop in childhood.

When pheochromocytoma is detected in childhood, the peak age is between 10 and 13 years, with a male predominance (male vs. female, 2:1) before puberty.[134] As in adults, pheochromocytoma in children usually presents with hypertension and symptoms of catecholamine excess. In contrast to adult patients, in whom sustained hypertension is found in only 50% of cases, more than 70% to 90% of children present with sustained hypertension.[135] Pheochromocytoma is the underlying cause in 1% to 2% of cases of pediatric hypertension and should be considered after exclusion of more common causes such as renal disease and renal artery stenosis. Sweating, visual problems, weight loss, polyuria, polydipsia, nausea, and vomiting are common in children.[136] Less frequent clinical manifestations include fever, constipation, headache, anxiety, syncope, cyanotic episodes, and those related to cardiomyopathy.

As in adults, measurements of plasma free metanephrines provide a highly sensitive (100%) and specific (94%) test for the diagnosis of pheochromocytoma in children.[137] However, the biochemical diagnosis of pheochromocytoma can be made difficult by stress-associated false-positive results during blood sampling and incomplete urine collections (when relying on 24-hour urinary excretion of metanephrines). While plasma concentrations of normetanephrine are lower in children than in adults, plasma concentrations of metanephrine are higher in children than in adults, and in boys than in girls. Thus, sex- and age-appropriate reference intervals for plasma metanephrines are also called for in children. This is most important for plasma normetanephrine, which shows a continuous upward trend with aging from 5 years of age onwards through adulthood.[138] The predominance of cluster 1 mutations among children is paralleled by a higher prevalence of noradrenergic tumors in children compared to adults; this is characterized by lack of increases in plasma metanephrine in 93.2% of childhood cases compared with 57.3% of adult cases.[126]

For the localization of pheochromocytoma in children and young adults, MRI is preferred over CT to limit radiation exposure. Additional functional imaging is recommended in children, considering a higher likelihood of multifocal disease. In the differential diagnosis of ^{123}I-MIBG-positive lesions, neuroblastoma should be considered.[139]

For the surgical management of pediatric pheochromocytoma, a laparoscopic approach via either the retroperitoneal or transperitoneal route is preferred.[140] Especially in children, in the setting of bilateral adrenal pheochromocytoma or a high chance of developing contralateral disease, for example in case of MEN2, cortex-sparing partial adrenalectomy should be considered to avoid adrenal insufficiency. The principles of perioperative and anesthesiologic management are similar in children and adults, on condition of age-appropriate use of medications.

Pheochromocytoma in Pregnancy

Pheochromocytoma in pregnancy is extremely rare, at one in 15,000 to 54,000 pregnancies, but carries a high risk of morbidity and mortality if the tumor remains undiagnosed antenatally.[141] Today, maternal and fetal mortality rates have decreased to 8% and 17%, respectively.[142] The clinical presentation of pheochromocytoma during pregnancy is similar to that outside pregnancy, and as gestation progresses, symptoms worsen, eventually culminating in a life-threatening catecholaminergic crisis. This applies in particular to the peripartum period. A clinical presentation with hypertension is usually ascribed to more prevalent pregnancy-related hypertensive syndromes such as (pre) eclampsia, resulting in missing the diagnosis of pheochromocytoma. Other clinical clues that may assist in differentiating pregnancy-related hypertension from pheochromocytoma are acute onset of symptoms, presentation in first 20 weeks of gestation, paroxysmal hypertension, paroxysmal headache, palpitations, and postural hypotension, all which are more likely in pheochromocytoma.[143] Patients known to have a previous history of pheochromocytoma or a mutation in one of the pheochromocytoma-associated susceptibility genes have a high *a priori* risk.

The biochemical diagnosis is not different from that in patients without pheochromocytoma, with measurement of plasma free or urinary metanephrines as the test of choice. If the diagnosis is biochemically confirmed, MRI is the preferred imaging method. Once the tumor is localized, it is recommended to remove the tumor by laparoscopy in the first 24 weeks of pregnancy after proper preoperative α-adrenoceptor blockade. In patients in whom the diagnosis is established in the third trimester, tumor removal is to be done at or after delivery.[141]

Although the optimal mode of delivery is controversial, in most cases elective cesarean section has been used as mode of delivery, as intensive labor during vaginal delivery has been considered a risk factor for cardiovascular complications. However, choice of delivery should be personalized depending on parity, previous cesarean delivery, success of pretreatment, and personal preference of the patient.[144] Therefore, management of this specific group of high-risk patients requires involvement of an experienced multidisciplinary team.

FUTURE DIRECTIONS

Multiomics approaches together with artificial intelligence will soon dominate large-scale national and international studies to better uncover the development, pathogenesis, and molecular biology of this tumor.[4] We also predict that algorithms using artificial intelligence approaches and novel bioinformatics technologies will result in better prediction of malignant potential in pheochromocytoma and an improved decision-making process for appropriate patient-tailored therapeutic options, surveillance, and ultimately its cure. Near future new treatments including demethylating agents, HIF-2α inhibitors, radiolabelled somatostatin receptor 2 antagonists, topoisomerase/PARP inhibitors, glutaminase inhibitors, and immune checkpoint inhibitors, as well as new theranostics approaches, will become reality.[122]

BACKGROUND AND HISTORY

Since Perry Sargent performed and reported the first planned adrenalectomy in 1914,[1] surgeons have developed multiple operative approaches. Early on, clinicians rarely knew if a large tumor causing local symptoms in the abdomen and retroperitoneum was of adrenal origin. Steady progress in the field and discovery of adrenal steroids (cortisol by Kendall and Reichstein in the 1940s,[2] aldosterone by Conn,[3] androgens and estrogens and catecholamines[4]) led to advances in surgical technique to account for the unique needs to address hormone excess and neoplasia. In 1926, Cesar Roux removed a pheochromocytoma by a flank approach. Seven months later, Charles Mayo did the same in the United States. In 1931, Broster described adrenalectomy by a thoracoabdominal approach. In 1936, Young described an open posterior approach, removing the eleventh and/or twelfth rib, providing access to the retroperitoneum and adrenal gland without having to traverse the contents of the peritoneal cavity or mobilize the liver or spleen. It was through a bilateral open posterior approach that Baum performed the first operation for primary aldosteronism (Conn syndrome).[5] The open posterior approach grew in popularity for this particular indication as it allowed for nearly direct access to relatively normal-size adrenal glands and a quicker immediate recovery, return of bowel function, and hospital discharge compared with an anterior approach.[6] Knowledge regarding malignancies affected by estrogens and androgens, such as breast and prostate cancer, led to favoring a posterior approach to facilitate removal of bilateral adrenal glands. This was one way to minimize circulating levels of androgens and estrogens prior to the development of medical therapies for this purpose.[7,8] Other modifications of approaches to the adrenal gland were reported in ensuing years.[9,10] More recently, in 1993, Makuuchi described an incision extending from just inferior to the xiphoid to several centimeters above the umbilicus and then extending laterally with the option for coursing between the ninth and tenth ribs to provide access to the pleural cavity if desired.[11] Modifications and extensions of all of these approaches have been described over the years.

In 1992, a major change in approach to adrenalectomy occurred when Gagner and colleagues in Canada and Higashihara in Japan reported adrenalectomy by a laparoscopic approach.[12-16] Since then, additional minimally invasive approaches have been described, including posterior retroperitoneoscopic, hand-assisted laparoscopic, and robot-assisted approaches. Technical aspects of these approaches continue to be refined. Currently, a minimally invasive approach is the gold standard for excision of the majority of benign adrenal lesions.[17,18]

With a significant increase in the number of adrenal abnormalities identified (4%–10% of patients undergoing imaging studies) due to the sharp rise in imaging of the chest and abdomen, proper evaluation and management has never been more important.[19] Additionally, it is recognized that the spectrum of adrenal hormone excess is much greater than previously shown.[20] Even with mild autonomous hormone secretion, detrimental effects result in a significantly increased risk of morbidity and mortality.[21,22] Early identification and treatment of hormone excess will become a focus for clinicians and researchers in the next decade. The most competent adrenal surgeons have a comprehensive knowledge of adrenal physiology and the biology and genetics of the many different adrenal disease processes, and are facile with numerous operative approaches to the adrenal gland.

PREOPERATIVE EVALUATION

A thorough history and physical examination, along with biochemical and imaging evaluation, is critical to correctly diagnose and manage patients with adrenal disorders.[23,24]

Clinical

Patients should be questioned about and examined for evidence of signs and symptoms suggestive of hormone excess, although a significant proportion with biochemical evidence of hormone excess or autonomous production will not have physical signs or symptoms (Table 100.1). In patients with possible adrenal cancer, either adrenocortical carcinoma or malignant pheochromocytoma, evidence consistent with possible metastatic disease should be sought prior to any surgical intervention. Clues to adrenal malignancy may include rapid or progressive weight gain or weight loss and lower extremity swelling due to occlusive tumor thrombus in the vena cava and potentially resulting in Budd–Chiari syndrome. Rare patients with adrenocortical carcinoma have an enlarged supraclavicular (Virchow's) node. Metastatic disease involving the vertebral bodies or impinging on the spinal cord or nerve roots may cause symptomatic fractures or neurologic impairment. Patients with large tumor burden and excess cortisol may have severe weakness, extreme hypertension, hypokalemia, or hyperglycemia. Lymphoma of the adrenal gland(s) may lead to localized symptoms or "B" symptoms (fever, weight loss, etc.). Signs of adrenal insufficiency may be evident if a malignant process (usually not of adrenocortical origin) obliterates the adrenal cortex.[25] This may also occur with infectious and autoimmune processes.

Thorough investigation of the patient's past medical history sheds light on the possibility of malignancy metastatic to the adrenal gland. Prior history of malignancy, family history, and new symptoms suggestive of malignancy should be reviewed, including pursuit of routine health maintenance investigations. While any malignancy theoretically can metastasize to the adrenal glands, malignancies that most commonly metastasize to the adrenal glands include melanoma and primary tumors of the lung, breast, and kidney. Colorectal cancer is less common, although reports are increasing.[26] Lymphoma may arise within the adrenal glands or metastasize to the adrenal glands.[27]

Infectious diseases may localize within the adrenal glands, the most common being tuberculosis, histoplasmosis, cryptococcosis, paracoccidioidomycosis, and cytomegalovirus. Abnormal response to synthetic adrenocorticotropic hormone (ACTH) stimulation tests or frank adrenal insufficiency dependent on the severity of human immunodeficiency virus/acquired immunodeficiency syndrome ranges from 14% to 54%.[28] On rare occasions, surgeons may be consulted to obtain tissue for confirmation when the adrenal gland is inaccessible to interventional image-guided biopsy, and no other sites exist or are amenable to biopsy.

TABLE 100.1 **Clinical Signs and Symptoms of Hormone Excess, Cancer, and Adrenal Insufficiency**

Hormone Excess or Disease Process	Signs and Symptoms
Aldosterone	Hypertension, hypokalemia, hypernatremia, edema
Cortisol	Moon facies, facial plethora, buffalo hump, muscular weakness, sarcopenia, fatigue, striae, hyperglycemia, weight gain, increased visceral adiposity, hypokalemia, hirsutism, hair loss, easy bruising, hypercoagulability, emotional lability
Androgens and estrogens	Change in secondary sexual characteristics
Catecholamines	Palpitations, hypertension, dyspnea, sudden-onset headaches, diaphoresis, hyperglycemia, pallor, tremor, anxiety
Adrenal cancer	Hormone excess, rapid weight gain or weight loss, pain, localized symptoms, lower extremity edema, hyperglycemia, hypertension, hair loss.
Adrenal lymphoma	Pain, adrenal insufficiency, fever, weight loss, and/or other "B" symptoms
Adrenal insufficiency due to gland obliteration	Fatigue, weight loss, nausea, diarrhea, vomiting, hyperpigmentation, hypotension, hyperkalemia, hyponatremia, weakness

Familial History and Genetic Testing

The discovery of genetic mutations leading to adrenal disorders has driven specific biochemical (adrenal vein sampling) and radiologic testing (NP-59, metaiodobenzylguanidine, and now DOTATATE–positron emission tomography [PET] computed tomography [CT]) to identify laterality of disease and inform surgical approach. A thorough family history should be taken at the time of the initial consultation. Genetic testing should be guided by risk, and in some cases, all patients with a certain type of tumor should be referred to a genetic counselor for consideration of genetic testing for a germline mutation, as in the case of pheochromocytoma and adrenocortical carcinoma.[29-32] In some situations, such as patients with pheochromocytoma, knowledge of disease driven by a germline mutation impacts concern for malignancy and surgical decision-making. In those with benign disease driven by a germline mutation (e.g., multiple endocrine neoplasia [MEN] 2, von Hippel–Lindau, neurofibromatosis), the surgeon should consider partial adrenalectomy to preserve cortical function for as long as possible. Each case is different, and the decision regarding extent of surgery must be individualized to the patient.

In addition to testing for germline mutations through bloodwork, investigation of mutations within the tumor itself can also be helpful. In those without a personal or family history concerning for an inherited mutation, testing for mutations within a resected tumor can provide valuable information. Certain mutations, such as those in *MSH* and *MLH* genes, may suggest Lynch syndrome and lead to testing for a germline mutation after surgery.[31] If a somatic mutation alone is noted on final pathology after surgery (given that biopsy preoperatively is to be avoided in general), that knowledge may inform future treatment decisions and therapies. Knowledge of the particular type of *SDH* somatic mutation in patients with pheochromocytomas or paragangliomas can provide clinicians with information as to the potential aggressiveness of a tumor and potential for recurrence and metastasis.[33] As adrenal cancers and the mutations driving them may be different in different areas of a tumor or change over time, repeat tissue sampling over the course of disease may be warranted to guide therapy. Some institutions accomplish this through in-house testing. A number of commercial offerings are also available.

Biochemical Evaluation

Assessment of adrenal hormone production is performed in a consistent and comprehensive fashion. Selection of individual tests based on a patient's clinical presentation can lead to misdiagnosis. In nearly 25% of cases of hormone excess, patients have subclinical disease. With a new understanding of the expanded spectrum of adrenal hormone dysregulation, especially in patients with primary aldosteronism and mild autonomous cortisol secretion, this percentage is likely even higher. Similarly, the suboptimal implementation of screening guidelines also contributes to the underestimation of the prevalence of adrenal hormone dysregulation.

Table 100.2 lists the steroid hormones and biochemical tests routinely ordered to assess hypothalamic-pituitary-adrenal (HPA) axis integrity and adrenal hormone production, including catecholamines from the medulla. Additional tests may be necessary, especially in the case of an indeterminate adrenal nodule possibly representing adrenocortical carcinoma (ACC). Intermediaries along the steroidogenesis pathway can be helpful in predicting malignancy.[34] Along these lines, the breakdown products of adrenal steroids and their intermediaries may also be measured in urine.[35] Urine steroid patterns have been found to aid in differentiating between benign and malignant adrenocortical tumors. Preoperative identification of hormone excess, including intermediaries, is important for postoperative care, and in patients with malignancies of adrenal origin may be used as tumor markers for recurrence or extent of disease.[36]

Imaging

In addition to biochemical data to understand the presence or absence of a functional disorder, the morphology of the adrenal glands is important in understanding adrenal pathology. Glands may be diminutive, enlarged, hyperplastic, have single or multiple nodules, contain cysts, contain calcifications, and/or show evidence of hemorrhage. While there is significant overlap, certain disease processes have certain radiologic characteristics that aid clinicians with diagnosis. Most commonly, adrenal protocol CT provides the most information pertinent to a surgeon[37-39]; however, adrenal protocol magnetic resonance imaging (MRI) also provides useful information.[40,41] From the standpoint of surgical planning, MRI is most often utilized to assess for evidence of vascular invasion of structures adjacent to adrenal cancers and intravenous tumor thrombus, and has greater sensitivity for identifying metastases to the liver. (^{18}F)-fluorodeoxyglucose (FDG)-PET/CT provides additional information in cases of adrenal nodules classified as "indeterminate" by CT or MRI.[42-45] Standard uptake value ratios of the tumor activity to the liver background and/or blood pool activity may be informative. Tumors metastatic to the adrenal gland have useful radiologic FDG avidity patterns; for example, renal cell cancers often have little FDG avidity. ^{11}C-metomidate PET is an additional study available outside the United States that may be utilized in differentiating benign from malignant adrenal tumors of cortical origin.[46,47]

Pheochromocytomas are most often heterogeneous or indeterminate based on intravenous contrast washout patterns on CT scan. Biochemical testing typically leads to the correct diagnosis and avoids the need to pursue additional imaging. FDG-PET/CT can reveal increased FDG uptake, and therefore is not particularly useful for distinguishing between a pheochromocytoma and malignant cortical tumor, or for distinguishing between benign and malignant pheochromocytomas. However, FDG-PET/CT may reveal metastatic disease, which would indicate malignancy. More recently, ^{68}Gallium-DOTATATE-CT has been shown to be the most sensitive of functional imaging studies in identifying tumors of neuroendocrine origin and determining extent of disease.[48-50]

TABLE 100.2 Biochemical evaluation

INITIAL ADRENAL BIOCHEMICAL EVALUATION

Routine	Consider
Complete blood count and metabolic panel	17-OH progesterone
ACTH	17-OH pregnenolone
Aldosterone	11-deoxycortisol
Renin	Androstenedione
1-mg DST with 8:00 AM ACTH, cortisol, dexamethasone level	Estradiol
24-hour urine free cortisol and creatinine	FSH, LH
DHEA-S	Progesterone
Testosterone (total or bioavailable)	Dopamine
Plasma and/or 24-hour urine metanephrine and normetanephrine levels	Chromogranin A

ACTH, Adrenocorticotropic hormone; *DST*, dexamethasone suppression test; *DHEA-S*, dehydroepiandrosterone sulfate; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone.

Fine-Needle Aspiration

There is a very limited role for fine-needle aspiration (FNA) of adrenal nodules.[23,51] The ability to discriminate between benign adrenal tissue and ACC is poor, and the undesirable possibility of seeding the needle tract with tumor has been reported. Treatment should be based on biochemical and radiologic imaging characteristics. FNA should only be pursued if it will change management. An indeterminate mass without evidence of metastatic disease will be resected almost regardless of FNA results. The most common circumstances for which FNA may be considered in patients with adrenal masses are: (1) patients who are poor operative candidates and need a diagnosis to guide additional treatment; (2) patients with suspected metastatic disease from a nonadrenal primary tumor in which the adrenal mass is the most easily accessible metastatic tumor deposit; (3) suspected adrenal lymphoma or abnormalities due to an infectious etiology (tuberculosis, histoplasmosis), which are often bilateral; (4) patients with presumed unresectable ACC and without evidence of hormone excess for whom tissue confirmation is necessary to guide neoadjuvant or palliative chemotherapy; and (5) if sarcoma is in the differential diagnosis, and neoadjuvant therapy would be pursued prior to resection. FNA in other situations is not particularly helpful. If FNA of an adrenal mass is pursued, pheochromocytoma must be ruled out before biopsy, as hypertensive crisis may result.[52] Similarly, retroperitoneal lesions along the axis of the body (e.g., along the spine, aorta, vena cava) that could be a paraganglioma should not be biopsied prior to biochemical assessment for elevated catecholamine production.[53]

TABLE 100.3 **Phases of Care in the Perioperative Period**

Preoperative	Intraoperative	Postoperative	Postdischarge
Medical control: blood pressure, hormone excess, electrolytes, glucose	Antibiotics, glucose control, blood pressure control, corticosteroids if indicated	For large incisions, consider antibiotics for 24 h; glucose; blood pressure; corticosteroids if indicated	Encourage mobilization, physical or occupational therapy as needed
Nutrition: emphasize protein intake	Care in positioning: skin, skeletal, nerves	Nutrition: emphasize protein	Nutrition: emphasize protein
Prehabilitation: Emphasize core muscle conditioning, walking, deep breathing; physical or occupational therapy if necessary	Complete resection, minimize trauma to surrounding structures (spleen, liver), intraoperative ultrasonography to help localize gland within retroperitoneal fat	Early mobilization, physical or occupational therapy as needed	Wean or reinstitute antihypertensive and diabetic medications as indicated, manage electrolytes, watch renal function
Select operative approach based on patient disease, surgical history, comorbidities, and anatomic factors	Incision care, minimize hematoma and fluid collections	Provide information before discharge regarding signs of cortisol withdrawal, Addison disease, how to obtain medical alert bracelet	Review pathology
Disease-Specific Considerations			
Cancer: staging, evaluate for metastatic disease **PPG**: genetic testing, preoperative blockade, and volume expansion	**Cortisol excess**: consider additional mechanisms for fascial closure, prevent wound infection **PPG**: communication with Anesthesia service during case to minimize hypertensive episodes, prior to clipping adrenal vein, volume resuscitation, management of hypotension	**Aldosterone**: hold BP medications, reinstitute if warranted, watch potassium and creatinine **PPG**: hold BP medications, reinstitute if needed, watch for hypoglycemia **Cortisol**: test for adrenal insufficiency, determine need for steroids	**Cancer**: genetic testing if ACC, determine need for additional treatment, develop survivorship plan **Aldosterone**: assess degree of clinical and biochemical resolution over first year **Cortisol**: wean corticosteroids as indicated if unilateral adrenalectomy, ensure corticosteroids and fludrocortisone if bilateral adrenalectomy **PPG**: genetic testing if not already completed, annual fractionated metanephrine levels

PPG, Pheochromocytoma paraganglioma; *BP*, blood pressure; *ACC*, adrenocortical carcinoma.

KEY POINTS

- A thorough understanding of relevant adrenal anatomy, physiology, and interpretation of radiologic findings, is critical to facilitate sound decision making regarding adrenalectomy.

DISEASE-SPECIFIC DECISION-MAKING FOR SURGERY

The decision to proceed with adrenalectomy is based on imaging characteristics, size, and evidence of hormone excess. Once a decision for surgery is made, a surgical approach can be chosen. Considerations for the preoperative care of patients are listed in Table 100.3.

Benign Nonfunctional Adrenal Tumors

In general, benign biochemically nonfunctional tumors of the adrenal gland, including enlarged hyperplastic glands, do not need to be removed. The size of the tumor alone should not dictate the need for adrenalectomy if benign and nonfunctional. In the past, tumor size greater than 4 or 6 cm alone was used as a cutoff, given an increase in rate of malignancy[24]; however, this view has changed over time, and currently imaging characteristics (taking into account washout percentages and other imaging characteristics) are considered in combination with size.[23] A purely nonfunctional tumor with benign imaging characteristics that is larger than 4 to 6 cm does not necessarily need resection based on size alone. A decision to pursue resection for benign-appearing nonfunctional tumors reaching 6 to 10 cm may be made, because tumors of this size are still potentially amenable to a minimally invasive approach. With increasing size, an open approach is more likely needed due to difficulty manipulating the tumor, identifying and preserving adjacent structures, avoiding disruption of the tumor capsule and rupture, and simply needing to extract the tumor from the peritoneal cavity. Morcellation of an adrenal tumor is contraindicated, as it obviates the possibility of adequate pathologic examination. Adrenal tumors can grow quite large (10–15 cm) prior to patients developing local symptoms. The true incidence of localized symptoms attributable to adrenal tumors based on size is not well known. These symptoms may not be apparent to the patient until after the tumor is removed and the patient has recovered from surgery.

Patient age and comorbidities should also be taken into consideration to aid in the decision-making process regarding resection of benign nonfunctional tumors. In young patients, continued follow-up over many years adds to medical costs, and the patient may prefer resection sooner rather than later, especially while still healthy and with few comorbidities. The issue of follow-up and nonoperative management of benign nonfunctional tumors, including hyperplastic glands without tumors, has been investigated by many groups. Achieving consensus regarding follow-up is challenging given the short follow-up period of many studies, when many patients are diagnosed with tumors in midlife. The most recent guideline recommendations from Europe suggest that a single follow-up imaging study is sufficient.[23] Two studies specifically addressed follow-up of adrenal tumors incorporating risk of malignancy, age, and cost of follow-up. Suh and colleagues performed a cost–utility analysis examining optimal follow-up from a cost standpoint.[53] A strategy of one-time follow-up in patients with "nonfunctional," radiologically benign tumors was superior to other strategies in patients with adrenal tumors smaller than 4 cm. In patients over 60 years old, one-time or no follow-up was found to be most cost-effective in this model. Limitations to this include lack of long-term follow-up over decades, as the assumptions in this study were based on data with follow-up for progression of 5 years or less. It is also unclear how many patients had full biochemical evaluation, including 1-mg dexamethasone suppression test (DST), to assess for hormone dysregulation. It is known that tumors larger than 2.5 cm can begin to autonomously produce small amounts of cortisol. It is becoming more apparent that even mild autonomous cortisol excess significantly increases risk of cardiovascular morbidity, infection, and death. While in years past it was unclear that there was an adenoma-to-carcinoma sequence in adrenal tumors similar to that associated with other types of malignancies, it has been documented within the past decade that adrenocortical carcinomas can arise from within adenomas.[54] The incidence of this is unknown. It is unclear if this mechanism dominates development of ACC or if ACC arises *de novo*, and what proportion of all ACCs it contributes to. While nonoperative management is most common, it may be reasonable to consider resection if the patient is younger to prevent the question of need for follow-up over a long period of time. If a neoplasm is nearing the limit for safe minimally invasive resection, it may also be reasonable to remove these tumors to prevent the need for a more invasive open resection if growth occurs. Wang et al. examined the cost-effectiveness of surgery for nonfunctional adrenal tumors based on size.[55] This study incorporated risk of malignancy and did not solely examine benign tumors. The study also did not stratify by imaging findings in terms of benign or indeterminate characteristics. They found that surgical resection based on size alone was cost-effective in patients with tumors greater than or equal to 4 cm or in patients under 65 years old. Whether or not this strategy holds for those with radiologically benign tumors is unknown.

Myelolipomas

The overwhelming majority of myelolipomas are benign, nonfunctional tumors. In rare instances, they may secrete excess adrenal hormone (most commonly cortisol).[56] For the most part, myelolipomas do not need to be removed if they are small and biochemically nonfunctional and do not cause bothersome local symptoms. Rare cases of malignant transformation have occurred, but it is not clear that at a population level this warrants changing recommendations for long-term follow-up. Growth may occur over time, and resection may be recommended, but as long as they remain benign and nonfunctional, observation is most often pursued. It is difficult to predict which neoplasms will grow and which will remain stable over time.

Adrenal Cysts

Patients with adrenal cysts need to be considered in a slightly different manner. Pure cysts without evidence of a solid component can often be observed. If small cysts less than 4 to 6 cm are growing slowly, and all other imaging characteristics are otherwise benign, aspiration with injection of ethanol can be considered for ablation. The long-term durability of this approach is approximately 30%, with decreased success rates as cyst size increases.[57] Cysts with a solid component harbor a small risk of malignancy, whereas in those with cystic areas within a larger, more solid tumor, the risk of malignancy is even higher because fluid-filled portions may be due to tumor necrosis or hemorrhage. Unlike pure cysts, the cystic portions of heterogeneous adrenal masses should not undergo aspiration of the fluid-filled portion of the tumor prior to or during surgery to decrease the tumor size, as this violates oncologic principles. Pheochromocytomas may show evidence of necrosis and fluid within the tumor. Biochemical evaluation will usually secure the diagnosis in these patients. Aspiration of any sort in these patients should be avoided as previously discussed.

Biochemically Functional Adrenal Disorders

Those patients with evidence of overt hormone excess due to a unilateral adrenal tumor, hyperplastic gland, or pituitary disorder are most often offered surgery rather than medical management. In patients with mild autonomous hormone secretion, the decision for surgery is more individualized and often dependent on hormone levels, morbidities, and expected duration of survival.

Hypercortisolism

The management of those with biochemical evidence of subclinical hormone excess can be more difficult than overt cases from a decision-making standpoint. Most patients with subclinical hypercortisolism are diagnosed by a DST.[58,59] For those with subsequent morning cortisol levels greater than 5 μg/dL, resection is usually pursued. For those with morning cortisol levels between 3 and 5 μg/dL, resection may be pursued in some.[60,62] Often, clinicians will assess sequelae of disease in this range to assist in the decision to pursue resection; however, there is compelling evidence from a number of studies revealing significantly increased risk of cardiovascular morbidity and mortality in these patients without classic signs of cortisol excess.[21,22] In those with post-DST morning cortisol levels 1.8 to 3 μg/dL, surveillance is most often pursued, but again, evidence of increased morbidity and mortality has also been described for this group of patients. The decision for operation in patients with dysregulated cortisol secretion should be made in the context of the severity of other potential disease processes that may be attributable to hypercortisolism, such as hypertension, diabetes, weight gain, and bone density loss. Studies reporting outcomes of patients with subclinical hypercortisolism do show benefit after adrenalectomy; however, many of these studies have methodologic flaws, and accurately differentiating patients with subclinical disease from those with overt hypercortisolism can be difficult.[62-65] For those with hypercortisolism due to bilateral excess adrenal production (ACTH-dependent or -independent disease and other types of hyperplasia), the decision for unilateral (starting with the largest adrenal gland) versus bilateral adrenalectomy should be made jointly by a multidisciplinary team including an endocrinologist.

For patients with hypercortisolism, exercise and consumption of a high-protein diet should be encouraged before surgery, given muscle deterioration due to the disease process. If time permits, several months of preoperative treatment with a cortisol-suppressing medication can be helpful in better controlling the quantity of cortisol excess. During surgery, patients with overt hypercortisolism should be given stress-dose steroids. If undergoing bilateral adrenalectomy, stress-dose steroids can be given after resection of the first adrenal gland. Alternatively, these may be held until several hours after the operation is completed to allow a decrease in cortisol levels to a more reasonable level in those with severe excess cortisol. A standard stress-dose steroid regimen is 50 to 100 mg of intravenous hydrocortisone every 8 hours. This is then tapered over several days to a defined dose to be given at the time of discharge in conjunction with the input of the managing endocrinologist while awaiting response of the HPA axis and return of autonomous function of the contralateral adrenal gland. Those with suspected subclinical disease may forego intraoperative stress-dose steroids if testing of the HPA axis is planned for the morning after surgery in the form of an early morning cortisol level or cosyntropin stimulation test.

Congenital Adrenal Hyperplasia

Several mutations affecting the presence and function of enzymes in the steroid synthesis pathway lead to congenital adrenal hyperplasia

(CAH).[66] Three phenotypes exist (two classical and one nonclassical), and patients have varying degrees of decreased cortisol, salt-wasting, and hyperandrogenism. Patients are most often identified in childhood but may present as adults. Depending on the severity, glucocorticoids and mineralocorticoids are often provided. Glucocorticoid administration also limits excessive secretion of both corticotropin-releasing hormone and ACTH, thereby minimizing the production of adrenal-derived androgens. These patients develop myelolipomas over time that can become quite large, necessitating resection. Growth can be asymmetric, but most often bilateral adrenalectomy is pursued. These patients are usually already on steroids, and so are used to taking additional medication, eliminating this as a reason to avoid bilateral adrenalectomy. The decision for and timing of surgery often depends on size of the myelolipomas that develop. Timing for removal may also depend on local symptoms, as well as the ability to perform a minimally invasive or hand-assisted approach rather than an open approach.

Bilateral Macronodular Adrenal Hyperplasia

As bilateral macronodular hyperplasia is often driven by a mutation leading to constitutive activation of a G protein–coupled receptor leading to cortisol excess, any remnant tissue will have the same mutation, leading to the same issue of autonomous cortisol secretion.[67] A common approach to surgery in these patients is to remove one adrenal gland and then determine if the remaining degree of excess cortisol production warrants contralateral adrenalectomy. Given that even small amounts of cortisol excess from dysregulated production are associated with significant risk for cardiovascular and neurologic morbidity, as well as death, bilateral adrenalectomy is pursued by some groups.[68,69,70] While cure of hypercortisolism is ensured, assuming all adrenocortical tissue is removed, this results in the need for lifelong steroid replacement. More recently, pursuit of unilateral adrenalectomy with contralateral subtotal adrenalectomy leaving a remnant of at least 30% up to a normal size gland has been reported. Cure of hypercortisolism without recurrence and without need for supplemental steroids was achieved in all patients who had undergone bilateral or subtotal adrenalectomy with a follow-up period of 40 months. Given that tissue remains, and the underlying cause is mediated by a mutation, the long-term durability of this approach for patients to remain eucortisolemic awaits further study. If any cortical tissue remains, persistent autonomous cortisol production will result, but the degree of hypercortisolism is difficult to predict based on the amount of tissue; therefore, understanding how much tissue to remove is also difficult. Residual tissue after subtotal adrenalectomy may hypertrophy and result in clinically relevant sequelae. Should patients develop recurrent hypercortisolism, they may be treated with medication until such time as completion adrenalectomy can be pursued.

Primary Aldosteronism

Patients with primary aldosteronism need further evaluation to determine whether surgical resection is appropriate. Traditionally, an aldosterone:renin ratio greater than 20 suggests the diagnosis in a screening setting (e.g., screening in a hypertension clinic), although the key to diagnosis remains a suppressed renin level. Recent data suggest that current guidelines for testing fail to identify many cases, and that cutoffs for absolute aldosterone levels may need to be lowered,[20] as our understanding of the true spectrum of disease has increased significantly. Most cases undergoing evaluation and surgery at this time can now be considered to be on the severe end of the spectrum, regardless of potassium level or number of hypertension medications. If hypertension and hypokalemia are present, a patient has likely had longstanding disease. Also recently described are aldosterone-producing cell clusters, which develop with age and autonomously secrete aldosterone.[71] Even with mild disease, risk of cardiovascular and renal morbidity and mortality is increased, and this occurs even prior to development of hypertension.[20] The diagnosis is mostly dependent on renin suppression when no other reason exists. Certain medications should be held before testing, as they can affect the renin level. Confirmatory tests such as saline or captopril suppression tests may be pursued. The Endocrine Society published guidelines detailing the biochemical evaluation of these patients.[72] CT imaging has been found to be poor in terms of specificity for unilateral versus bilateral excess aldosterone secretion from the adrenal glands. Specificity averages approximately 40% to 50%.[73] Therefore, once a clear biochemical diagnosis has been made, adrenal vein sampling should be pursued in most patients to determine the unilateral or bilateral nature of the excess hormone production.[72,73] Understanding how to interpret these studies is critical, as is having an interventional radiologist with high success of entering the left adrenal vein and especially the right adrenal vein. Aside from those with hormone excess, the decision for operation should also be based on the physical status of the patient and existing comorbidities. Some patients can be easily medically managed, and this may be more appropriate in patients with significant comorbidities. Scoring systems have been developed to estimate the likelihood of complete clinical cure; however, the generalizability to other cohorts has been questioned. Additionally, it is not simply the improvement in blood pressure and heart rate that is important. A reduction in aldosterone is also extremely important, and has only recently been recognized.[20] Inappropriate activation of the mineralocorticoid receptor leads to adverse effects in multiple organ systems, increasing cardiovascular and neurologic morbidity and mortality with or without hypertension.

For those with primary aldosteronism, improved control of hypertension is often best achieved with spironolactone or eplerenone. Creatinine, renin, sodium and potassium levels should be closely followed while titrating these medications. In addition to potassium supplementation, hypokalemia (which occurs in ~50% of patients) may also be controlled in part with amiloride. If patients are hypokalemic in the immediate preoperative setting, lower doses than normal should be given as replacement if needed, due to the potential for rebound hyperkalemia in the postoperative setting.

Androgen- and Estrogen-Secreting Tumors

No specific preoperative preparation is required prior to removal of these tumors. Of adrenocortical carcinomas secreting hormones, testosterone is the second most common type after cortisol. An adrenal mass with indeterminate imaging characteristics with evidence of excess androgen secretion is presumed to be ACC until assessed by a pathologist. In rare circumstances, large, indeterminate androgen-secreting adrenal masses are found to be benign. Androgen-secreting tumors may be found in the pediatric population, and may be found at an earlier stage if precocious puberty or ambiguous secondary sexual characteristics are noted.

Pheochromocytoma

Preoperative preparation for resection of pheochromocytoma is critical. Due to improved preoperative preparation, intraoperative anesthetic management, and postoperative care, outcomes have dramatically improved since the mid-20th century, when mortality rates were close to 50%.

Patients should be given detailed information regarding the risks of resection of pheochromocytoma and advised that adherence to instructions for blockade and hydration are critically important to follow. Communication with the physician managing this aspect of care is also critical. Blockade may begin when the patient is diagnosed, as it is likely they have been referred for hypertension. For those without

TABLE 100.4 Medications for Preoperative Blockade of Pheochromocytoma and Paraganglioma

Drug	Starting Dose
Alpha Blockade	
Phenoxybenzamine	10 mg BID or TID
Doxazosin	2 mg QHS
Beta Blockade	
Propranolol	20 mg TID
Atenolol	25 mg QD
Calcium Channel Blockade	
Nicardipine	20 mg TID
Nifedipine	30 mg QD (shorter half-life)
Amlodipine	5 mg QD
Catecholamine Synthesis Inhibitor	
Metyrosine	250 mg QID

BID, Twice a day; *TID*, three times a day; *QD*, daily; *QHS*, nightly; *QID*, four times a day.

hypertension, blockade may be delayed until closer to surgery. Rarely, patients may present with dopamine-secreting pheochromocytomas or paragangliomas. If secreting dopamine only, preoperative blockade is not necessary.[74,75] Medications that can be utilized for blockade are listed in Table 100.4.[32] A gradual shift from phenoxybenzamine (PBZ) to doxazosin has occurred over time. In part, this is due to the high cost of PBZ, lack of coverage by some insurance companies, lack of stock in some pharmacies, and more severe side effects. However, many surgeons continue to prefer alpha blockade with PBZ in patients with highly active tumors and severe hypertension. With alpha blockade, patients should liberally hydrate to expand the intravascular volume as vasodilation occurs. Patients should understand that nasal stuffiness, fatigue, and occasional dizziness are expected. Titration of blockade should not stop when these symptoms occur, but should instead continue until an appropriate goal blood pressure is reached. As alpha blockade and vasodilation progress, the heart rate may increase. Fluid administration should decrease the heart rate as euvolemia is reached. If volume does not decrease the heart rate, and additional blood pressure control is needed, a beta-blocker can be instituted. In patients with minimal to no hypertension, a calcium channel blocker is an alternative. This has even fewer side effects than selective alpha blockers, but does not cause any significant vasodilation. The effect on blood pressure is less than that of alpha- and beta-blockers. Intraoperative hypotension after ligation of the adrenal vein can be greater, as vasodilation occurs all at once in the operating room rather than predominantly over a slower period of time in the preoperative setting. Metyrosine is a tyrosine hydroxylase inhibitor that decreases catecholamine production. While its routine use has been described, it is seldom necessary.[76,77] The onset of effect is slow, given that bodily stores of catecholamines need to be depleted before effect is seen. Metyrosine is not commonly stocked in pharmacies and is expensive. It is most often utilized in patients with extremely difficult-to-control pheochromocytomas that require more control than can be gained with standard alpha, beta, and calcium channel blockade.

Blockade goals for systolic pressures below 120 mm Hg are ideal, but may be higher dependent on the situation, patient comorbidities necessitating a higher goal perfusion pressure, and/or degree of catecholamine secretion. Preparation for the operating room should begin no later than 1 to 2 weeks prior to surgery. In those with other comorbidities, especially cardiac, pulmonary and/or renal, where fluid shifts and changes in blood pressure could cause issues, slow blockade for a longer period of time is useful. Some literature exists suggesting that preoperative blockade of patients with pheochromocytomas is not necessary in some patients. The risk–benefit ratio favors routine blockade and is safest for the patient.[32]

Hyperglycemia due to catecholamine excess may be present in some patients with pheochromocytoma paraganglioma (PPG). Catecholamine stimulation of beta-receptors leads to gluconeogenesis, and stimulation of α2 receptors results in decreased release of insulin. Insulin resistance occurs in musculoskeletal tissue. The phenomenon is more often associated with larger tumors and those with greater production of epinephrine compared with norepinephrine.[78] Epinephrine-secreting pheochromocytomas may be more likely to induce glucose intolerance or frank diabetes mellitus due to a preferential affinity for the β receptor. Postoperatively, patients may experience hypoglycemia as excess catecholamine production ceases and rebound hyperinsulinemia results from a reduction in α2 receptor stimulation.[79,80] Improved peripheral insulin sensitivity with increased glucose use by skeletal muscle further contributes to hypoglycemia.[81] Postoperative hypoglycemia after resection of pheochromocytoma was reported in 4.2% of patients in one study.[78] The hypoglycemia is temporary, treated with intravenous dextrose as needed if more than oral consumption of food is needed, and usually resolves in 1 to 2 days at the most.

Adrenocortical Carcinoma

Up to 50% of patients with ACC have evidence of hormone excess. This is likely an underestimation given a high frequency of inadequate biochemical evaluation. Hormone excess should be managed as best as possible to optimize safety for surgical resection and facilitate postoperative recovery.[83] For those with suspected or obvious ACC, a chest CT should be obtained as part of the routine preoperative evaluation to evaluate for metastatic disease.[30] In those with metastatic disease, resection is usually delayed in favor of chemotherapy and mitotane, with a select few being able to undergo resection if all sites of disease can be addressed in some form or fashion (medical or procedural). In part, chemotherapy allows for time to understand the tumor biology and tempo of disease. Regression or stability indicates that resection may be beneficial, whereas progression and development of additional sites of disease indicates that resection of the primary tumor is unlikely to impact overall survival, and the patient will spend 2 to 3 months recovering from surgery if no complications prolong recovery. Those with locally invasive tumors, where an R0 resection would be less likely, may benefit from neoadjuvant chemotherapy and mitotane for at least two cycles, and possibly more depending on response.[83]

Metastatic Disease to the Adrenal Gland

Patients with metastatic disease to the adrenal glands should be carefully evaluated with regard to their overall prognosis and planned future therapy. There is ample evidence to suggest benefit of adrenalectomy for resection of a malignancy metastatic to the adrenal gland if it is the single site of disease.[84] Other indications may be a growing adrenal mass that could result in local invasion of adjacent structures or other issues when other disease is stable or being controlled with another treatment modality. Those with additional metastatic disease elsewhere may be better served by other treatment modalities. Some malignancies are quite radiosensitive, and in the situation of an aggressive cancer with poor prognosis, focused radiation therapy or other types of local intervention may be more appropriate; however, these are not recommended as first- or second-line therapy.

SURGICAL APPROACHES TO THE ADRENAL GLAND

The individual patient's anatomy should be carefully studied when selecting an operative approach. The operative approach is not solely based on size alone, but also includes prior surgical history, concern for malignancy, need for access to other intraabdominal organs, planned concomitant procedures elsewhere in the peritoneal cavity, cardiac and pulmonary status in terms of toleration of a lateral or prone position, body habitus, and position of the adrenal gland with respect to the renal vasculature and upper pole of the kidney from the standpoint of selecting an anterior or posterior approach. Important anatomic features to consider when choosing between a laparoscopic and retroperitoneoscopic approach are listed in Table 100.5. An attempt to control hormone excess and correct electrolyte abnormalities should be pursued if possible. Medications to assist in curbing excess hormone production in advance of surgery are listed in Table 100.6.

The most common indications for selection of an open approach cited in two reviews were contraindications to laparoscopy, tumor size greater than 5 cm, increasing body mass index, and contraindications related to specific disease processes.[17,86,87] Somewhat counterintuitively, Lee et al. reported that patients included in the Veterans' Affairs National Surgical Quality Improvement Program registry undergoing open adrenalectomy had considerably higher preoperative risk than those selected to undergo laparoscopic adrenalectomy.[88] Buell et al. reported a series of 48 patients who underwent bilateral adrenalectomy for hypercortisolism by anterior or posterior open approaches from 1985 to 1997.[89] Operative time, blood loss, and need for transfusion were equal. Acute morbidity was similar. Long-term morbidity was greater in those undergoing an open posterior approach. Patients required more pain medicine for longer, had increased chronic back pain, and took longer to return to work. Table 100.5 compares anterior, posterior, flank, and thoracoabdominal approaches to adrenalectomy.

As indications and approaches to adrenalectomy changed over time, so too did outcomes. Complication rates (increases and decreases) related to changes in treatment (new therapies, new techniques) vary over time.[87] Different treatment approaches bring with them the potential for new or unique complications. This is illustrated in longitudinal studies by Sidhu et al.[90] and Lo et al.[91] Comparisons of various approaches to adrenalectomy can be difficult to carry out due to patient comorbidities and risk, provider and hospital-level differences, and selection bias related to choosing one approach over another. When comparing costs and complications associated with various approaches to adrenalectomy, the data vary widely, with some finding comparable costs and complication rates for various open and minimally invasive approaches and others finding significant differences. Hospital stay is generally longer for open approaches, but can be comparable dependent on the disease process being treated. A significant variation in cost has been found at the level of preoperative evaluation as opposed to the operation itself.[87,92,93]

Adrenalectomy may be accomplished by a number of approaches. Most commonly, for small benign tumors, a laparoscopic transperitoneal approach is preferred. An alternative approach, for those with experience in adrenal surgery, is the posterior retroperitoneoscopic approach.[94] The spleen and liver do not need to be mobilized, and blood loss is often diminished due to increased insufflation pressures

TABLE 100.5 Comparison of Operative Approaches to the Adrenal Gland (Anterior, Posterior, Flank, Thoracoabdominal, Anterior/Posterior Minimally Invasive +/- Robotic Assistance

Approach	Advantages	Disadvantages
Open		
Anterior	Access to entire peritoneal cavity, facilitates multivisceral resections, appropriate for vascular bypass, can make multiple incisions. Approach of choice for malignancies. Access to both adrenal glands	Increased pain, wound infections, hernias, adhesions from prior surgery, ileus, hospital stay
Flank	Can extend between floating ribs, can remain fully retroperitoneal if desired	Difficult to access superior gland if incision is below twelfth rib, poor access to remainder of peritoneal cavity. No access to contralateral gland
Posterior	Avoids scar tissue from prior intraperitoneal operations. Access to both adrenal glands. Faster recovery than open anterior approach. No mobilization of liver or spleen/pancreas	Limited access, difficult to remove large tumors, limited vascular control, no multivisceral resection other than kidney. Possible chronic pain, nerve entrapment, abdominal wall laxity
Thoracoabdominal	Simultaneous access to thorax and abdomen. Advantageous when remobilizing liver, spleen, or pancreas after prior operation. Good access to aorta and vena cava	Largest, most painful incision, possible chronic pain due to nerve entrapment. Entry into chest
Minimally Invasive		
Anterior (laparoscopic transabdominal)	Supine or lateral position. Less pain, shorter hospital stay, fewer wound infections. Faster recovery. Access to most organs of the peritoneal cavity	If lateral positioning, no access to contralateral gland.
Flank (transabdominal or retroperitoneal)	Retroperitoneal approach avoids intraperitoneal scar tissue. Allows for removal of larger tumors than posterior retroperitoneoscopic approach	Limited working space, limited access to peritoneal cavity, limited ability for multivisceral resection or vascular control. Patient in lateral position
Posterior (retroperitoneal)	No lifting restrictions, less pain, fastest recovery, less bleeding, access to both glands without repositioning	Limited space, difficult to resect large tumors. Different view with definite learning curve
Hand-assisted	Allows for removal of larger tumors, pressure on tumor from retraction spread over wider area	Larger incision than laparoscopic approach. Visualization can be impeded by presence of hand
Robot-assisted	Increased degrees of freedom for wristed motion compared with minimally invasive instrumentation. Better ergonomics for surgeon	Often more expensive, longer operations. Less rapid exchange of instruments. Surgeon is not at bedside

TABLE 100.6 Medications to Minimize Adrenal Cortex Hormone Excess

Hormone in Excess	Medication	Mechanism	Starting Dose	Notes
Aldosterone	Spironolactone	MR antagonist	25 mg QD	Titrate slowly to BP, potassium, renin, and creatinine
	Eplerenone	MR antagonist	50 mg QD	Titrate slowly to BP, potassium, renin, and creatinine
	Amiloride	Antikaliuretic-diuretic	5 mg QD	Avoids rise in renin if performing diagnostic testing and/or AVS
Cortisol	Ketoconazole	Inhibits 11β-hydroxylase, 17-hydroxylase, and 17,20-lyase	200 mg QD	Not effective for moderate to severe hypercortisolism
	Metyrapone	Inhibits 11β-hydroxylase	250 mg Q4 hours	Monitor cortisol and 11-deoxycortisol levels
	Osilodrostat	Inhibits 11β-hydroxylase and aldosterone synthase	2 mg BID	Monitor cortisol levels, titrate slowly
	Mifepristone	Cortisol receptor blocker	300 mg QD	Cannot use cortisol level to monitor receptor blockade (leads to increased cortisol levels); monitor by symptoms and glucose
	Etomidate	Inhibits 11β-hydroxylase	0.04 mg/kg per hour intravenously	Requires ICU monitoring
	Mitotane	Inhibits cholesterol side-chain cleavage enzyme, 11β-hydroxylase, 18-hydroxylase, and 3β-hydroxysteroid dehydrogenase	1 g BID	For use in patients with adrenal cancer; also an adrenolytic; derivative of the insecticide DDT
Androgens	Spironolactone	MR antagonist	25 mg QD	Abiraterone and ketoconazole are alternatives
Estrogens	Tamoxifen	Estrogen receptor antagonist	5 mg QD	Raloxifene, anastrozole, letrozole, exemestane are alternatives

MR, Mineralcorticoid receptor; *QD*, every day; *AVS*, adrenal vein sampling; *Q4*, every 4 hours; *BID*, twice daily; *DDT*, dichlorodiphenyltrichloroethane.

and the need for less mobilization of overlying structures. This approach also allows for access to both adrenal glands without repositioning, reprepping, and redraping during bilateral laparoscopic transperitoneal adrenalectomy. Postoperative pain can be less and recovery quicker. However, the retroperitoneoscopic approach does not allow for multivisceral resection or adequate access to the peritoneal cavity. Those with significant renal insufficiency may experience further worsening of their glomerular filtration rate due to the increased insufflation pressures. Robotic assistance may be used for either laparoscopic or retroperitoneoscopic approaches.[95] For those patients with larger tumors not amenable to a purely laparoscopic or laparoscopic hand-assisted approach, those with tumors concerning for primary adrenocortical carcinoma, those with prior surgery in the upper retroperitoneum, or those needing multivisceral resection or concomitant intraperitoneal procedures, an open transabdominal approach using a subcostal or midline incision is usually pursued. Although used frequently in the past, the open posterior approach is rarely used anymore, but remains a useful approach-especially in those who have undergone prior surgery in the upper quadrants. Finally, a thoracoabdominal approach to the adrenal glands may also be used but is rarely needed, except in the situation where access to the chest and abdomen is required or there has been significant prior surgery in the area and an open posterior or posterior retroperitoneoscopic approach is not possible. Most often, these situations involve patients with extensive invasive or recurrent malignant adrenal tumors.

KEY POINTS

- The surgical approach to adrenalectomy should be chosen carefully and customized to the individual patient, taking into consideration the specific disease process and type of hormone excess, radiologic findings, concern for malignancy, patient anatomy and comorbidities.

OPEN ANTERIOR TRANSABDOMINAL

Right

Because open adrenalectomy is most often performed for malignant tumors, this section will describe the operative approach from an oncologic standpoint. Although a midline incision can be made, a wide right subcostal incision extending to the left side is favored because of an improved ability to retract the ribs and mobilize the liver, providing exceptional access to the adrenal gland, kidney, and vena cava. The peritoneal cavity is inspected in a systematic fashion. Intraoperative ultrasound of the liver and evaluation of the adrenal vein and vena cava for tumor thrombus may be performed. The attachments to the liver are divided and the right lobe of the liver rotated medially. A retractor (Omni or Thompson most often) is placed to provide exposure. Through the surface of the posterior peritoneal lining, the kidney and the adrenal gland are able to be appreciated. If the tumor is found to be invading the posterior aspect of the liver, a rim of normal liver may be resected *en bloc* as part of the anterior margin. As delineated in Fig. 100.1A, dissection occurs inferiorly over the superior half of the kidney, taking the posterior peritoneal lining and any fat over the superior half of the kidney to provide an ample inferior margin. This is continued to the plane found between the adrenal gland and kidney. If there is any concern for the invasion of the kidney, removal of a portion of the capsule of the kidney or partial or complete nephrectomy may be performed, depending on the extent of suspected invasion, because one does not want to create a plane between tumor and the surface of the kidney where none exists, allowing for microscopic abrasion and dissemination of tumor cells. Dissection is continued laterally to the abdominal sidewall, and all retroperitoneal fat surrounding the tumor is taken as part of the lateral and posterior margins, with dissection exposing the posterior musculature. Dissection continues superiorly to the diaphragm. Some of the diaphragm may be excised *en bloc* with the tumor if necessary and closed in standard fashion with a running locking suture. Occasionally, mesh is required for closure of a large defect. The medial dissection is then performed. Dissection begins over the anterior aspect of the vena cava. The fat medial to the tumor is then taken as part of the specimen, including any fat or lymph nodes posterior to the renal hilum and vena cava and along the lateral surface of the aorta. Working superior to inferior and inferior to superior, the adrenal vein is eventually identified, ligated, and divided in standard fashion. If invasion of the vena cava is identified, various methods can be used to resect portions of vein to provide negative medial margins or extract tumor thrombus, including resection and

replacement of a segment of the vena cava with ringed polytetrafluoroethylene graft. Venovenous or cardiopulmonary bypass may be needed in some cases. The tumor is then removed and marked with sutures. Clips can then be placed if radiation therapy will be considered in the future. The abdominal wall is closed in two fascial layers along with suture to approximate the deep subcutaneous tissue. A running suture or staples can be used for skin closure.

Left

Similar to the right side, a wide subcostal incision is made (Fig. 100.1B). The colon is mobilized along the white line of Toldt. The splenic flexure and spleen are then released from their attachments to the lateral side wall diaphragm to the esophageal hiatus. The stomach, spleen, pancreas, and colon are then retracted medially, exposing the kidney, left adrenal gland, and aorta. Conduct of the operation on the left side is similar to that of the right side, taking all surrounding and retroperitoneal fat in the area with the adrenal gland.

KEY POINTS

- Surgeons need to ensure performance of the critical elements of resection for adrenocortical carcinoma, with surgery best carried out in high volume centers given surgery for benign adrenal disorders is quite different than for adrenocortical carcinoma.

OPEN FLANK–TRANSABDOMINAL OR RETROPERITONEAL

With the patient in a lateral position (full or partial), a transabdominal or retroperitoneal approach may be taken (Fig. 100.2). The incision may extend between the eleventh and twelfth ribs, the twelfth rib may be removed, or the incision may be placed beneath the twelfth rib, although this approaches the adrenal from the most inferior aspect, and the surgeon may struggle to reach the superior aspect of the adrenal gland. The surgeon may traverse the peritoneum from this approach or may choose to remain extraperitoneal, mobilizing the ascending colon on the right or the descending colon, splenic flexure, spleen, and pancreas on the left to access the organs and structures of the retroperitoneum. The adrenal is then removed in similar fashion to the more standard open anterior approach.

OPEN POSTERIOR (LUMBOTOMY)

The patient is placed in a prone position. A curvilinear or angled incision is made as shown in Fig. 100.3, extending from medial to lateral along the course of the twelfth rib. The twelfth rib is identified and removed. The retroperitoneum is entered. It is important to sweep the retroperitoneal fat from superior to inferior and from medial to lateral to identify and preserve the diaphragm and locate the gland. Because of the location, the pleural cavity may inadvertently be entered and may be sutured-closed. Using handheld retractors to retract the ribs and musculature, the kidney is identified and retracted inferiorly with the surgeon's hand, and the adrenal gland identified medially and superior to the renal hilum. Adrenalectomy is performed, albeit from a dorsal approach, in standard fashion. The wound is closed in multiple layers, making sure not to injure the neurovascular bundle of the eleventh and twelfth ribs.

LAPAROSCOPIC ANTERIOR TRANSABDOMINAL

Right

The patient is placed supine, sometimes with a gel roll or rolled blanket under the right side, as shown in Fig. 100.4A. Port sites are triangulated using standard techniques for access. On the right side, four ports (occasionally more) are most often placed, one of which is for retraction of the liver. The triangular and coronary ligaments of the right lobe of the liver are divided, and the liver is retracted medially. An alternative approach is to forego mobilizing the attachments to the lateral and superior aspect of the liver and instead retract the liver anteriorly to dissect around the adrenal gland. This approach is less ideal than the lateral transadominal approach, especially for larger masses, as it limits working space and access to the adrenal gland. The upper pole of the kidney is identified, and the space between it and the adrenal gland is identified. The vena cava is also identified. Intraoperative ultrasound scanning can be useful for identifying the adrenal gland when abundant retroperitoneal fat is present. The attachments of the periadrenal fat are released from the upper pole of the kidney using standard techniques, most often ultrasonic dissection. It is critical to identify and remove the most inferior extent of the adrenal gland, which sometimes overlies the renal vasculature, as even a small amount of hormonally functional tissue can lead to persistent disease. Once the inferior attachments have been released, some of which may include small vessels coming off the renal artery or renal vein, the dissection continues superomedially along the vena cava until the adrenal vein is identified. Options for ligating and dividing the adrenal vein include ultrasonic instruments, clips, and sometimes a stapler if access is difficult or the vein is wide. The more superior attachments medially and laterally are then released, and the adrenal gland is removed. Port sites are closed in standard fashion. The operation is more difficult than when the patient is in a lateral decubitus position due to lack of aid from gravity to help allow the liver to fall away from the adrenal gland to the contralateral side. However, if the use of hand assistance with a gel port is anticipated, or the potential for risk of conversion to a laparoscopic approach is high, this may be a more optimal approach.

Left

Four ports (occasionally more) are most often required for left adrenalectomy (Fig. 100.4B). The splenocolic ligament is divided, and the colon mobilized inferiorly and medially. The remaining splenic attachments are then mobilized to the esophageal hiatus so that the spleen will remain mediatized, often without the need for a retractor. Left adrenalectomy is then carried out in similar fashion to the right side. The left adrenal vein is usually identified in the 7 o'clock position. This may be visualized on preoperative imaging in many cases. A communicating branch may course longitudinally from the adrenal vein to the phrenic vein along the medial aspect of the adrenal gland. Attachments of the adrenal gland to the surrounding tissue are ligated and divided, and the adrenal gland is removed. Similar to the right side, the supine positioning impedes the spleen from falling away to the right side away from the adrenal gland, and a retractor is necessary. An alternative approach is to avoid mobilizing the lateral and superior attachments and instead retract the tail of the pancreas and spleen anteriorly to allow for dissection around the adrenal gland. This approach limits access to the gland and working room.

LAPAROSCOPIC LATERAL TRANSABDOMINAL ADRENALECTOMY

Right

The patient is placed in left lateral decubitus position at a 45-degree or greater angle, as shown in Fig. 100.5A, so that the abdomen and flank are accessible if conversion to an open procedure is necessary. The space between the ribs and pelvis is extended. Port sites are triangulated using standard techniques for access. On the right side, four ports (occasionally more) are most often placed, one of which is for retraction of the liver. The triangular and coronary ligaments of the right lobe of the liver are divided, and the liver is retracted medially. The upper pole of the kidney is identified, and the space between it and the adrenal gland is identified. The vena cava is also identified. Intraoperative ultrasound scanning can be useful for identifying the adrenal gland when abundant retroperitoneal fat is present. The attachments of the periadrenal fat are released from the upper pole of the kidney using standard techniques, most often ultrasonic dissection. It is critical to identify and remove the most inferior extent of the adrenal gland, which sometimes overlies the renal vasculature, as even a small amount of hormonally functional tissue can lead to persistent disease. Once the inferior attachments have been released, some of which may include small vessels coming off the renal artery or renal vein, the dissection continues superomedially along the vena cava until the adrenal vein is identified. Options for ligating and dividing the adrenal vein include ultrasonic instruments, clips, and sometimes a stapler if access is difficult or the vein is wide. The more superior attachments medially and laterally are then released, and the adrenal gland is removed. Port sites are closed in standard fashion.

Left

Three ports (occasionally four or more) are most often required for left adrenalectomy (Fig. 100.5B). The splenocolic ligament is divided and the colon mobilized inferiorly and medially. The remaining splenic attachments are then mobilized to the esophageal hiatus so that the spleen will remain medialized, often without the need for a retractor. Left adrenalectomy is then carried out in similar fashion to the right side. The left adrenal vein is usually identified in the 7 o'clock position. This may be visualized on preoperative imaging in many cases. A communicating branch may course longitudinally from the adrenal

vein to the phrenic vein along the medial aspect of the adrenal gland. Attachments of the adrenal gland to the surrounding tissue are ligated and divided, and the adrenal gland is removed.

LAPAROSCOPIC HAND-ASSISTED ADRENALECTOMY

In patients with moderately to significantly enlarged benign adrenal tumors, an intermediate option between minimally invasive and standard open surgery is incorporation of hand assistance with laparoscopic visualization and instruments. Attempts to remove large tumors laparoscopically are more prone to tumor capsule disruption. The ability to mobilize the tumor is hampered by difficulty with visualization, limited working space, and at times the sheer weight of the tumor. While an open approach usually allows for excellent access and working space, a larger incision is associated with a higher incidence of wound infection, longer hospital stay, and greater chance of incisional hernia. An intermediate option with growing appeal is a laparoscopic hand-assisted approach utilizing a hand port to allow for manipulation of surrounding organs and the tumor with one hand while the other hand utilizes the usual laparoscopic instrumentation for division of soft tissue and vasculature (Fig. 100.6). Given that morcellation of adrenal tumors is to be avoided, enlargement of at least one incision is required for extraction of the tumor. For tumors greater than 6 to 8 cm, the size of the incision needed for extraction will admit a small- to medium-sized hand. Adrenalectomy performed with hand assistance for moderate to large tumors can often be performed faster than those performed by conventional laparoscopy. Incisions, while larger than those for a pure laparoscopic approach, but smaller than those required for an open approach, are associated with fewer wound infections, less postoperative pain, fewer incisional hernias, and shorter hospital stay.

LATERAL RETROPERITONEOSCOPIC ADRENALECTOMY

In this least often utilized approach for adrenalectomy, the patient is placed in a lateral decubitus position. A 10-mm camera port is placed in the midaxillary line, followed by two 5-mm working ports for additional instruments in the anterior and posterior axillary lines (Fig. 100.7). Because access is obtained less posteriorly than in a dorsal retroperitoneoscopic approach, it is important to avoid entering the peritoneal cavity. The upper pole of the kidney is mobilized and separated from the inferolateral aspect of the kidney, and the rest of the dissection performed similarly to that discussed previously. Dissection medially may be more difficult, especially on the right side, because the gland will be resting on medial structures (vena cava and aorta) more so than compared with anterior, posterior, or lateral transabdominal cases, where the patient is not in full lateral decubitus position. This particular approach has the advantage of permitting a retroperitoneal approach in patients with higher body mass index or tumors of larger size where a dorsal retroperitoneoscopic becomes more difficult.[96] This approach can also be useful in those with dense scar tissue in the upper abdominal quadrants due to prior surgery. Hand assistance may be utilized with this retroperitoneoscopic approach, unlike with the dorsal retroperitoneoscopic approach.[97]

POSTERIOR (DORSAL) RETROPERITONEOSCOPIC ADRENALECTOMY

The patient is placed in a prone position, as shown in Fig. 100.8. An initial incision is made near the tip of the twelfth rib. Blunt dissection into the retroperitoneal space is pursued. The retroperitoneal fat is bluntly swept from the musculature using a finger, allowing for placement of a 5-mm port near the tip of the eleventh rib laterally and a 10-mm port medially at the lateral edge of the erector spinae muscles approximately 30 degrees inferior to the original incision. The retroperitoneum is insufflated to a pressure of 20 to 22 mm Hg. This

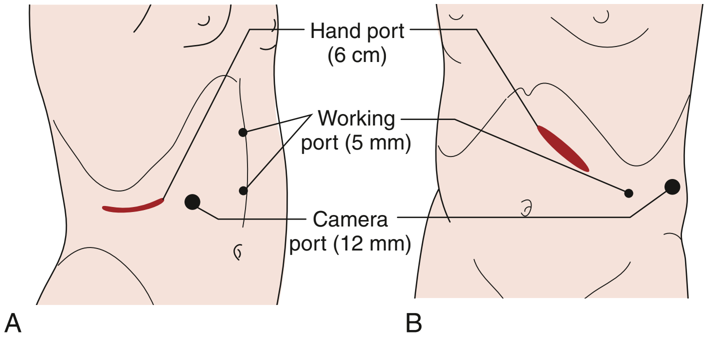

Figure 100.6 Gel port used for hand-assistance: right (**A**) and left (**B**).

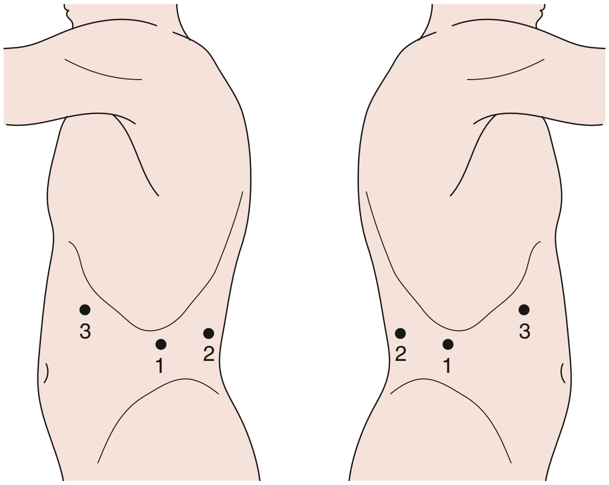

Figure 100.7 Port placement for lateral retroperitoneoscopic adrenalectomy.

can be increased if needed to assist with control of oozing or bleeding up to approximately 30 mm Hg. Areolar connective tissue is bluntly dissected from the posterior musculature, and the dissection carried medially and superiorly. As dissection and exposure proceed, the hue of the liver will be seen superolaterally. It is important not to dissect into the peritoneal cavity, because visualization becomes extremely difficult with loss of insufflation of the retroperitoneal space. Once the adrenal gland is identified, dissection should proceed from an inferior to superior fashion. On the right side, surgeons should proceed with caution during the medial dissection until the vena cava is clearly identified, because it will be compressed due to increased insufflation pressures. Because the right adrenal vein often emanates from the posterolateral aspect of the vena cava, it will be visualized more anteriorly in this approach than in a traditional laparoscopic approach, given the prone positioning. The adrenal vein is ligated and divided, and the remaining attachments are released. The adrenal is removed, the fascia of the middle port site is reapproximated, and the incisions are closed. A similar approach is taken for left retroperitoneoscopic adrenalectomy. The hue of the spleen is identified superolaterally, and dissection is carried out as described. The left adrenal vein can be more difficult to identify than the right adrenal vein due to the proximity of the left renal vein and a more posterior position compared with the traditional transperitoneal approach. With all laparoscopic and retroperitoneoscopic procedures, it is important to avoid disturbing the capsule of the adrenal gland, because this will lead to bothersome oozing during the case, which may obscure visualization. Some literature suggests that partial adrenalectomy is appropriate in select situations. This should be very carefully considered and performed by a high-volume adrenal surgeon, because there are nuances to the decision-making and conduct of the operation.

ROBOT-ASSISTED ADRENALECTOMY

Recently, enthusiasm has been increasing for utilization of computer-aided devices to perform minimally invasive adrenalectomy. The main advantage is that of the wristed motion afforded by certain instrumentation on the various robotic platforms. With computer-aided surgery, the adrenals can be reached from anterior, posterior, and lateral approaches. Collision of robotic “arms” can be an issue, and placement of incisions in close proximity can be an issue in some cases. An additional port for use by the “assistant” remaining at the bedside is utilized by some surgeons to more easily switch out instruments when needed. Costs may be increased, but strategies to mitigate this have been put in place by some surgeons.[98,99]

THORACOABDOMINAL APPROACH TO ADRENALECTOMY

Large tumors, tumors with extension into the thoracic cavity, need for control of the infracardiac suprahepatic vena cava, or patients who have undergone prior right upper quadrant surgery with severe scar tissue limiting access and remobilization and rotation of the liver may benefit from a thoracoabdominal incision. However, for the vast majority of adrenalectomies, including many of the listed situations, a less invasive approach, including more standard open approaches, is more than sufficient. A thoracoabdominal incision is the most painful of all incisions used for adrenalectomy and is associated with prolonged recovery and a greater chance for postoperative morbidities (Fig. 100.9).

DISEASE-SPECIFIC CONSIDERATIONS AND DECISION FOR EXTENT OF ADRENALECTOMY

The most common indications for surgery involve a single tumor or adrenal gland needing removal. In a minority of cases, partial unilateral, unilateral with contralateral partial, or bilateral adrenalectomy may be most suitable for treatment of a patient’s specific condition.

BILATERAL ADRENALECTOMY

The ultimate approach chosen by the surgeon for bilateral adrenalectomy is dependent on multiple factors. Time in the operating room can be lengthy, especially if a laparoscopic transabdominal approach is selected, as patients need to be repositioned, reprepped, and redraped in the middle of the case. An open anterior approach does not require this but is associated with higher wound infection rates, greater pain,

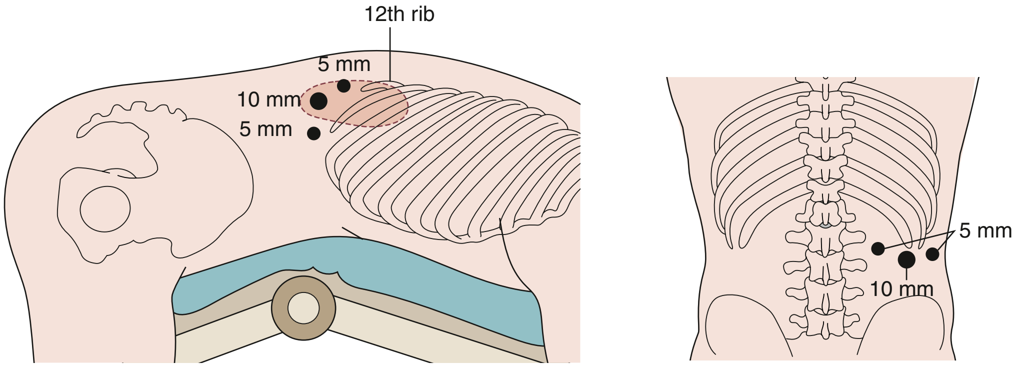

Figure 100.8 Patient positioning and port site placement for posterior retroperitoneoscopic adrenalectomy.

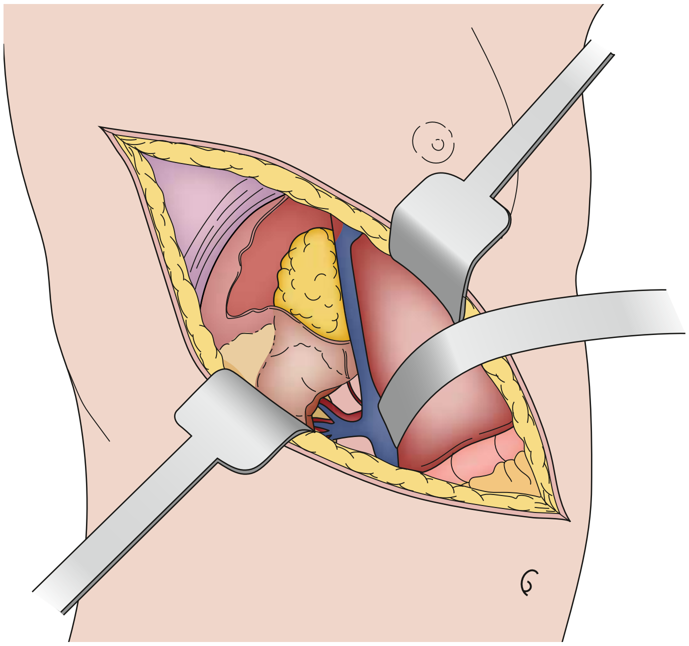

Figure 100.9 Positioning and incision for thoracoabdominal approach to adrenalectomy.

longer hospital stay, and longer recovery. Bilateral open posterior adrenalectomy, the most popular approach for many years prior to development of minimally invasive techniques, has advantages compared with open anterior approaches but is no longer learned or utilized by many surgeons, as it has been supplanted by the retroperitoneoscopic posterior approach. However, the open posterior approach remains useful for those not familiar with the retroperitoneoscopic approach, when prior surgery or complications have disrupted the normal planes in the retroperitoneum, or when conversion to an open approach is needed and the patient is already in a prone position.

PARTIAL ADRENALECTOMY

In the case of adrenal tumors possibly resulting from a genetic mutation, patients should be referred to a genetic counselor. Ideally, those suspected of having a genetic mutation would undergo this testing in the preoperative setting, as knowledge of the specific mutation can impact preoperative testing and conduct of the operation. Adrenal tumors may be found in patients with MEN 1. ACC is identified in patients with Li–Fraumeni syndrome (p53 mutation). Pheochromocytoma is associated with MEN 2A, MEN 2B, neurofibromatosis, and von Hippel–Lindau syndrome. Patients who are potential candidates for partial adrenalectomy should be referred to a surgeon with expertise in the disease process, the decision-making process, and the nuances of partial adrenalectomy. Partial adrenalectomy is most often performed in patients with pheochromocytomas resulting from a genetic syndrome. Given that tumor development is driven by a mutation, many of these patients develop tumors and symptoms at a young age, and tumors can eventually involve both adrenal glands. Given that both glands may become abnormal, rather than remove the entire gland with the tumor and normal adrenal tissue, an attempt can be made to spare adrenal cortical tissue to avoid the need for corticosteroids and the potential for Addisonian crisis. Quality of life is also reduced in patients on lifelong steroid replacement. The surgeon must carefully select patients for cortical-sparing adrenalectomy. The position of the tumor within the gland, the amount of remaining adrenal tissue, the venous outflow that will be disrupted during surgery and that will remain after surgery, as well as what will be anticipated in any future reoperative completion adrenalectomy must be considered (Fig. 100.10). Where the remnant will be in relation to the vena cava, aorta, and/or renal hilar vasculature may impact the approach to the initial surgery to allow for easier future reoperation. Remobilization of the liver after a transabdominal approach can be difficult, especially if the first operation was done as an open approach; a subsequent posterior approach may be easier at

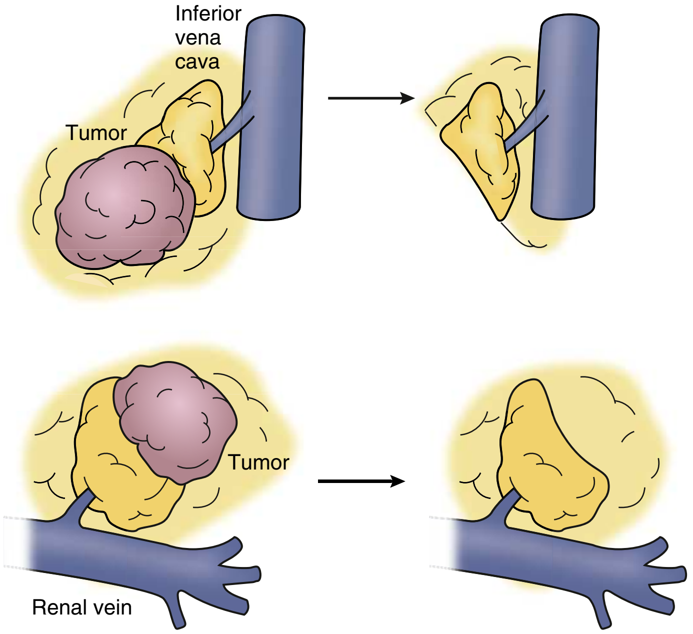

Figure 100.10 **Partial adrenalectomy.** Multiple tumor positions within the adrenal gland are amenable to partial adrenalectomy, and each must be considered individually with regard to vascular inflow and outflow, expected size of the residual remnant, and difficulty of any expected reoperation.

the time of reoperation, especially if the remnant ends up positioned posterior to the vena cava. Similarly, if a remnant is likely to reside near the renal hilum, it may be best to approach the initial operation posteriorly to allow for an anterior approach at the time of reoperation. At least 30% of a normal gland should remain if the hope is for cortical function not requiring supplemental steroids. During dissection, it is extremely important to avoid dissection of the entire periphery of the gland, and instead concentrate on confining dissection to the area of the portion of gland to be removed and avoid disruption of small vessels providing inflow and outflow to the portion of the gland that will remain. Indocyanine green can be utilized to assess perfusion of the remnant.

DISEASE-SPECIFIC INTRAOPERATIVE CONSIDERATIONS

Considerations for the intraoperative care of patients are listed in Table 100.4.

Extent of Resection for Primary Aldosteronism. Despite some reports suggesting that partial adrenalectomy is associated with similar success compared with total adrenalectomy, the recommendation for total unilateral adrenalectomy remains for patients undergoing surgery for primary aldosteronism. Outcomes reported by some groups suggesting equivalence in these studies were of a short-term nature, and the degree of cure according to the Primary Aldosteronism Surgical Outcomes group reporting structure is unclear. Recent work on the molecular side illustrates the concern of performing partial adrenalectomy. Approximately 10% of adenomas identified on CT do not produce aldosterone when stained by immunohistochemistry for Cyp11b2 (aldosterone synthase).[100] It is elsewhere in the gland that excess aldosterone is being produced. Even if the adenoma is producing excess aldosterone, other areas in the gland may also be autonomously producing aldosterone, whether areas of hyperplasia, other microadenomas unable to be appreciated on preoperative imaging, or aldosterone-producing cell clusters. In addition, it is now known that, with age, areas of aldosterone-producing cell clusters can autonomously produce aldosterone. It is impossible at this time to reliably predict in advance the site(s) of production of aldosterone. Some have suggested the possibility of superselective venous sampling. Given the new knowledge of the distribution of autonomous aldosterone production within the adrenal glands and the variable venous outflow from aldosterone-producing areas within the gland, not to mention named and unnamed venous structures visible intraoperatively, less than complete adrenalectomy based on imaging or superselective venous anatomy cannot be recommended at this time.[99,100]

Hypercortisolism. During the preoperative timeout, discussion should center on electrolyte and glucose management, as well as expected blood loss. Positioning with ample padding of pressure points is necessary given the increased risk of skin breakdown due to cortisol excess. A discussion about any necessary steroid administration should occur. As a general rule, patients with overt signs of cortisol excess will require steroid supplementation in the postoperative period. Cortisol may be administered intraoperatively, but in severe cases with significant excess may be held until several hours after surgery given that the half-life of cortisol is 1 to 2 hours (depending on cortisol levels and degree of excess). Surgeons should work in concert with endocrinology colleagues to devise an appropriate plan tailored to the patient.

For patients with mild autonomous cortisol secretion, postoperative supplementation may or may not be needed. In general, intraoperative steroid administration can be avoided to facilitate testing of the HPA axis and need for steroids the morning after surgery. Dexamethasone administration by the anesthesia service to prevent postoperative nausea and vomiting should be avoided in these cases, as the large doses given will potentially interfere with morning cortisol levels depending on the amount given and the timing of surgery.

Pheochromocytoma. Good communication between surgical, anesthesia, and operating room staff is imperative when removing a

TABLE 100.7 Critical Elements of Resection of Adrenocortical Carcinoma

Element	Description	Additional Details
Exploration	Fully explore the peritoneal cavity unless limited by scar tissue	
Complete R0 resection of the primary tumor and periadrenal fat	Resection to microscopically negative margins without disruption of the tumor capsule	The adrenal gland and tumor, surrounding retroperitoneal fat, Gerota's fascia, and overlying peritoneum should be resected *en bloc*
En bloc resection of involved adjacent organs	Resect adjacent organs (fully or partially) if directly invaded by or adherent to the primary tumor	Creation of an artificial plane between the primary tumor and an adherent or invaded structure should not be attempted
En bloc resection of involved vasculature and/or tumor thrombus	Dependent on extent, utilize bypass, liver perfusion, and/or circulatory arrest as needed, with or without reconstruction	Most often refers to the renal veins, renal arteries, and/or vena cava. Tumor thrombus may extend into the right atrium
Therapeutic lymphadenectomy	Abnormal lymph nodes noted on imaging or intraoperatively. Examine periadrenal, perirenal, aortocaval lymph nodes.	An extended prophylactic lymphadenectomy is not recommended. The station(s) of origin of any resected lymph nodes should be specifically noted in the operative report

pheochromocytoma. Preoperative timeouts should include a discussion of goals of fluid administration before and after adrenal vein ligation, potential for blood loss, goals for blood pressure management, and available agents for treating hypertensive and hypotensive episodes. The anesthesia team should be notified, if possible, prior to ligation of the adrenal vein to allow time for transition of blood pressure agents for anticipated hypotension and increased fluid administration. Fluid administration is the first method to increase blood pressure. Vasopressors may be required in some patients to maintain a mean arterial pressure greater than 60 mm Hg. Alpha agonists may not work well, or increased amounts may be required, depending on the degree of preoperative alpha blockade. Vasopressin is an alternative that works well in many cases. Hypotension often resolves by the end of the case, but may persist over the first 24 hours.

Adrenocortical Carcinoma. Given the aggressive tumor biology, resection of ACC differs from resection of benign adrenal masses with regard to the recommended technical components of resection. Aside from removal of the entire tumor or gland depending on the disease process, there are no specific recommendations for benign adrenal processes. Because of the high chance of local tumor recurrence, peritoneal dissemination, and poor prognosis, technical aspects of resection play a primary role in ACC. Table 100.7 lists the technical elements of resection that must be performed. Multivisceral resection is often required, as is management of vascular involvement, necessitating some form of reconstruction. The American College of Surgeons Operative Standards for Cancer Surgery has set the standard for technical aspects of resection and has evaluated several areas of debate, including operative approach, surgery in stage IV patients at the time of presentation, and the utility of prophylactic lymphadenectomy.[101] It is also recommended that in addition to a detailed operative report, a synoptic operative report also be recorded in the medical record to capture aspects of the operation in a consistent format.

On occasion, unsuspected metastatic disease may be noted upon exploration of the peritoneal cavity. In this situation, long-term prognosis is usually quite poor. A decision to abort the operation is most often made, but there could be instances where a decision to proceed is made. This decision hinges on the volume of disease and the ability to resect all disease. Resection of the primary tumor and all metastatic disease followed by early institution of mitotane, and possibly etoposide, doxorubicin, and cisplatin (EDP), could be pursued.

There has been significant debate over the past 10 years regarding the operative approach to adrenalectomy for ACC, and an open approach remains the recommended approach for resection of ACC. If a surgeon were to consider a minimally invasive approach for resection of a small (<6 cm) ACC, the following conditions would need to be satisfied: the individual surgeon has considerable experience with both laparoscopic adrenalectomy and surgical resection of ACC, can ensure performance of the critical elements as described, and can produce acceptable oncologic outcomes.[101] Few surgeons meet these requirements at this time.

Performance of prophylactic lymphadenectomy at the time of resection of the primary tumor is not recommended despite some calls to do so.[101] The vast majority of patients with stage IV disease do not undergo surgery; however, there is a highly select group of patients that may benefit from resection of the primary tumor. Selection is key and requires careful assessment to understand tumor biology, tempo of disease, and other factors to gauge the expected long-term durability of surgical intervention. Often, treatment of patients with stage IV disease with EDP with mitotane for at least two rounds with restaging will provide an understanding of patients in whom surgery will not be of benefit, if progression of metastatic disease has occurred, versus patients who are noted to have regression or stability, in whom surgery could be considered. Performance status also plays a significant role in the decision for surgery in these patients. One must also consider the length of time during which metastatic disease will be unable to be treated with chemotherapy after surgery or if complications occur.

Reoperative Surgery for Adrenocortical Carcinoma. The decision for surgery in patients with recurrent ACC is complex. The disease-free interval, tumor grade, quality of initial resection, location of recurrent tumor, anticipated operation required to remove recurrent disease, ability to treat all recurrent disease, and fitness of the patient to tolerate reoperation all enter into the decision for reoperation. Even if an operation is technically feasible, the tumor biology may dictate avoidance of surgery and pursuit of systemic therapy instead. Recurrence after reoperation for an initial recurrence reaches a rate of 70% to 94%, and many times disease recurs in the same organ.[102,103] Therefore, there is now a greater emphasis on performing tissue-sparing procedures by nonsurgical means, including radiofrequency ablation, cryoablation, regional therapy, external beam radiotherapy, and stereotactic body radiation therapy. Long-term durability of reoperation to control hormone excess is often poor, but can be beneficial in select patients. The usually short increase in survival (3–6 months) may not be significant when length of time to recover from surgery and any surgical complications is considered from a quality of life standpoint.

Surgical Complications

With the volume of adrenalectomies performed having increased over time, the influence of surgeon adrenalectomy volume on complications has been recently reviewed.[104] Just over 80% of patients undergo adrenalectomy by a low-volume surgeon. This same study found that 82% of surgeons performing adrenalectomy completed an average of one adrenalectomy per year.[105] This raises concern regarding the understanding of endocrine physiology, as it can be quite nuanced and affect decision for surgery and the extent of surgery. A significant difference became apparent in complication rates at the level of six adrenalectomies per year.[106] However, this does not indicate that surgeons performing more than six adrenalectomies per year are high-volume adrenal surgeons. While there are no specific data to support a particular cutoff, at least one group suggests that a high-volume surgeon performs at least 30 adrenalectomies per year.[30] Similarly, technical abilities alone do not necessarily indicate familiarity with a particular disease process, type of hormone excess, or ability to have expertise in treating malignant adrenal disease.

Intraoperative Complications

Overall, intraoperative and postoperative surgical complications are few. Intraoperatively, complications may be the result of technical errors, physiologic derangements secondary to underlying hormone excess, and unrelated preexisting comorbidities. Cardiac complications are infrequent. In the past, the morbidity and mortality after resection of pheochromocytomas was extremely high. With improved preoperative care, modern anesthetic and surgical techniques, and postoperative care, cardiac morbidity and mortality are quite rare. Bothersome bleeding from the adrenal gland itself may occur if the capsule is penetrated. Other sources of brisk bleeding can result from laceration or puncture of surrounding solid organs such as the kidney, liver, spleen, pancreas, short gastric vessels, and the occasional small vascular structure coursing through the splenic and hepatic flexures or retroperitoneal fat. Massive bleeding may result from disruption of named vascular structures, including the renal veins and arteries, adrenal vessels, vena cava, aorta, phrenic vessels, hepatic veins, and splenic vessels. Interestingly, posterior retroperitoneoscopic approaches are associated with less blood loss compared with anterior or lateral transperitoneal approaches. This is due to the ability of the increased insufflation pressures utilized to create the retroperitoneal space to overcome the low venous pressure of the vessels at greatest risk.

Perforation of hollow viscus structures may occur due to inadvertent puncture or thermal injury during minimally invasive or open approaches. Similarly, the diaphragm may be penetrated, and the pleural cavity entered. This is usually easily repaired, and most often does not require chest tube placement. During resection of ACC, resection of a portion of the diaphragm may be necessary, and in many cases can make superior dissection easier, also allowing for development of a superomedial plane from which to dissect inferiorly along the vena cava or aorta. Dissection along the aorta and vena cava can lead to lymph and chyle leak. Output can be high, reaching a liter or more daily. Careful ligation of lymphatic structures is imperative.

Minimally invasive operative approaches with use of CO_2 gas for insufflation of the peritoneal cavity or retroperitoneal space can lead to CO_2 embolism. Insertion of a trocar into the liver or a venous structure may also result in CO_2 embolus. Pulmonary embolus from deep vein thrombosis (DVT) rarely occurs intraoperatively. Tumor thrombus in the vena cava in patients with ACC can embolize, but is remarkably stable in many cases. Patients with cortisol excess are at higher risk for DVT and pulmonary embolism, and consideration should be given to postoperative DVT prophylaxis for several months. The increased risk is not simply due to obesity resulting from cortisol excess, but also to the hormone itself.

Postoperative Complications

Complications common in the postoperative period are those common to other surgical procedures, and have been reported to reach a rate of 20%, although this varies according to approach, disease process, and surgeon volume.[104,105] Postoperative bleeding requiring return to the operating room is rare, as is wound infection. Superficial wound infections are less common when a minimally invasive approach is taken compared with an open approach. Patients producing excess cortisol are at higher risk for wound infection and development of incisional hernias. Hernias are more common with open approaches than with minimally invasive approaches.

Change in renal function may result from hypovolemia and inadequate volume resuscitation during or after surgery. In addition, small arterial branches may be inadvertently or unavoidably ligated during dissection along the superior aspect of the renal hilum. If nephrectomy is anticipated in a patient with preexisting renal insufficiency, a renal perfusion scan may be obtained preoperatively to determine if contralateral kidney function will allow for avoidance of hemodialysis. In some cases, this will inform the decision for or against proceeding with surgery versus systemic therapy in ACC patients. An interesting phenomenon occurs after adrenalectomy for primary aldosteronism. Renal function is often overestimated in the preoperative setting, especially in those either not placed on or suboptimally managed on mineralocorticoid receptors, given a hypervolemic state. Once excess aldosterone production is controlled with adrenalectomy and a euvolemic state is achieved, the amount of fluid filtered by the kidneys is less, and the true state of renal function is able to be appreciated. Operative approach can also affect renal function, although this is usually transient. In patients undergoing posterior-approach retroperitoneoscopic adrenalectomy, increased insufflation pressures can limit urine output during the operation and also result in acute renal insufficiency. These changes usually quickly resolve in the first 24 to 48 hours but could be an issue in patients with stage 3 or 4 renal insufficiency.

Hyperkalemia sometimes occurs. This may be noted in the rare case of acute renal insufficiency or failure, but is much more common in patients who have undergone adrenalectomy for primary aldosteronism. If the zona glomerulosa of the contralateral adrenal gland is suppressed due to excess aldosterone production from the gland being removed, the potassium level may rise substantially, even to a level requiring treatment. Measurement of potassium levels in the postoperative setting for at least the first 2 weeks is warranted.[106] A significant percentage of patients requiring temporary fludrocortisone while awaiting resumption of production of normal levels of aldosterone are identified in the first 2 weeks after discharge of the patient from the hospital.

Complications and Operative Approach

Operative approaches have advantages and disadvantages from the standpoint of risk of morbidity. Open approaches are often associated with greater risk of morbidity, but selection bias plays a part, as patients often have larger tumors, require multivisceral resection, or have other reasons for why a minimally invasive approach has not been chosen.

When comparing minimally invasive anterior approaches with posterior approaches, there are some differences in complications and outcomes. Posterior approaches are generally associated with less blood loss. The increased insufflation pressures decrease venous bleeding. In addition, some believe that the increased insufflation pressures may limit outflow of catecholamines during resection of pheochromocytomas and minimize significant intraoperative swings in blood pressure, thus representing another difference in approach leading to differences in outcomes and management. Given the access points and that dissection is confined to the retroperitoneum, development of an incisional hernia is not of major concern when a posterior approach is taken. Lifting restrictions are not required as they are with an anterior approach. An exception is if penetration of the peritoneal cavity is inadvertently made, but bowel herniation would be rare in this situation as well. Finally, many patients experience change in sensation around the incision site(s), there may be a higher incidence of broader changes in sensation when posterior approaches are utilized. The neurovascular bundle of the twelfth rib may be compressed, leading to sensory deficits in the distribution of the entire dermatome as it proceeds anteriorly from the site of the incision.

DISEASE-SPECIFIC POSTOPERATIVE CARE AND FOLLOW-UP

Considerations for the care postoperative care of patients are listed in Table 100.4.

Pheochromocytoma. Patients operated on for pheochromocytoma may experience hypotension over the first 24 hours as the effects of decreased catecholamine secretion and vasodilation are encountered. Fluid should be administered to provide volume repletion. Alpha agonists may be required, but, due to preoperative alpha blockade, often do not result in significant effect or require more than usual to overcome the blockade. Vasopressin is a useful alternative if needed. Hypotension is often avoided or experienced to a lesser degree and for a shorter period of time if preoperative alpha blockade and volume expansion are optimized pre- and intraoperatively.

Hypoglycemia may also be noted in the immediate postoperative period, as previously discussed.[78-80] Pathology should be reviewed. If patients have not undergone genetic testing preoperatively, they should be referred to a genetic counselor for assessment. If invasion into adjacent structures is noted intraoperatively, lymph node involvement is noted or reported in the pathology report, or metastatic disease is identified in a patient without a germline mutation, testing of the tumor itself can be pursued to identify a potential driver mutation. Malignant pheochromocytomas are often more frequent and more aggressive when due to *SDHB* mutations compared with other *SDH* mutations.

Primary Aldosteronism. Patients having undergone adrenalectomy for primary aldosterone often experience changes in volume status and electrolytes in the postoperative setting. The degree of this is in part dependent on the severity of disease and degree of preoperative control of hypervolemia and hypokalemia with medication. Patients should be monitored for changes in potassium levels. The effects of excess aldosterone begin to resolve within the first 24 hours. Dependent on whether or not the patient was cured, whether there is excess contralateral gland aldosterone secretion, and what medications are taken, potassium levels may stabilize, decrease, or increase after surgery. Significant diuresis related to decreased aldosterone levels can result in hypokalemia. Longstanding suppression of aldosterone secretion from the contralateral adrenal gland can result in hyperkalemia.[106] Some patients may require fludrocortisone in the postoperative setting if potassium levels are significantly elevated or hyponatremia or volume depletion is noted. Changes in potassium levels usually become apparent within anywhere from 12 hours to 2 weeks. Intermittent assessment and appropriate handoffs to other providers are warranted.

Blood pressure should also be assessed in the postoperative setting. In most patients, all blood pressure and potassium supplements are usually stopped, aside from clonidine and similar medications (which would result in severe rebound hypertension) and/or beta-blockers if utilized for cardiac-related issues. Blood pressure should be tracked closely in the first few days to assess the need for reinstitution of antihypertensive medications. Different classes of drugs may be required, dependent on the situation and dependent on cure of the primary aldosterone.

Creatinine levels may increase and glomerular filtration rate may decrease acutely after surgery. While intraoperative hypotension or ligation of an accessory renal artery or other complications may result in changes in creatinine, it is more likely that creatinine increases due to a decrease in glomerular filtration as hypervolemia resolves. With excess aldosterone, sodium and water retention ensue. The volume cleared by nephrons decreases with the resolution of excess aldosterone, resulting in decreased glomerular filtration rate and increased creatinine.

The final outcome of surgery can best be determined much longer after surgery than previously thought. It is now recognized that aldosterone levels may change over several months after surgery, as can blood pressure, potassium, and need for medication. Most outcome studies report data based on measures taken within 2 weeks of surgery. It is likely that many outcomes reported in the past are inaccurately reported due to lack of long-term follow-up. In 2016, the Primary Aldosteronism Surgical Outcomes group established recommendations for assessing and reporting outcomes.[107] Outcomes are stratified by clinical and biochemical outcomes and at multiple timepoints, with the last measurement 1 year after surgery. Aldosterone, renin, blood pressure, potassium, and creatinine should be checked on an annual basis at the time of the annual visit with a primary care physician. Future studies will hopefully be able to more accurately report outcomes, as indications for surgery and goals for clinical and biochemical outcomes will likely change.

Hypercortisolism. Steroid replacement in patients with hypocortisolism after surgery is critically important and a lifesaving measure while awaiting return of HPA axis function. In those having undergone bilateral adrenalectomy, steroid replacement is a lifelong necessity. Patients should be counseled prior to discharge regarding when and how to take steroids to replicate the diurnal rhythm as much as possible, with an early morning surge. Doses after 5:00 PM are avoided if possible, as this can impact sleep. Timing of administration may vary depending on the patient's individual situation, occupation, and timing of work shifts. Administration twice daily is most common, but regimens once or three times a day may be pursued, depending on the patient. It is advisable to utilize hydrocortisone in the postoperative setting when weaning will occur instead of prednisone, given the shorter half-life and ability to wean more quickly.

In patients who have undergone unilateral adrenalectomy, temporary full replacement (15–20 mg hydrocortisone total daily, which is then weaned) is usually necessary in patients who presented with overt signs and symptoms of Cushing syndrome, or in those with 24-hour urine cortisol levels above the normal range and suppressed ACTH. Return of HPA axis function may take 1 to 2 years in these patients before they can be weaned off steroids.[108,109]

In those who have mild autonomous cortisol secretion based on a 1-mg overnight dexamethasone suppression test and normal 24-hour urine cortisol and are without overt signs of hypercortisolism, some patients will need steroid supplementation. Postoperative testing is important in these patients. How and when to test are variable, ranging from testing cortisol the morning after surgery to formal stimulation testing with a synthetic derivative of ACTH(1–24) (Cosyntropin) up to several days after surgery.[60,110-113] Signs of cortisol insufficiency include lethargy, fatigue, weakness, nausea, poor appetite, hyperkalemia, hyponatremia, and volume depletion.

Patients with overt hypercortisolism often have significant musculoskeletal weakness and sarcopenia. Physical therapy to aid in restoring patients to their condition prior to developing hypercortisolism is underutilized and should be pursued. Changes related to adverse effects of hypercortisolism are slow to resolve, but do in general over the first 2 years.[108,109,113,114] While the body adjusts to a return to normal cortisol levels and rhythms, subjective reports of fatigue, nausea, and poor appetite are normal but usually resolve. Patients should be counseled preoperatively regarding this expected time course.

Adrenocortical Carcinoma. Pathology should be reviewed, and results, concerns about intraoperative events, or surgery-related morbidities impacting future care should be discussed between providers, preferably as part of a multidisciplinary tumor board.[30] Staging should be completed if necessary depending on the extent of preoperative need for adjuvant therapies, including external beam radiation, mitotane, and/or chemotherapy, surveillance, and survivorship should be addressed. Patients with hormone excess prior to surgery should be treated as discussed above. For patients placed on mitotane after surgery as part of adjuvant therapy, institution of this should start approximately 6 weeks after surgery if the patient has sufficiently recovered. Gastrointestinal side effects are common, and ensuring adequate nutrition is imperative to allow for full recovery in the months after surgery. Thyroid function and liver function must be monitored when patients receive mitotane. In addition, given that mitotane is an adrenolytic, glucocorticoid replacement is necessary.

Bilateral Adrenalectomy

Patients undergoing bilateral adrenalectomy require steroid replacement to prevent death. In the vast majority of patients, both glucocorticoid and mineralocorticoid replacement are required. Mineralocorticoid replacement is usually not required in patients receiving daily doses of glucocorticoids greater than 40 to 50 mg daily of hydrocortisone or an equivalent dose of another type of glucocorticoid.

Postoperatively, hydrocortisone is preferred for replacement over prednisone, given faster recovery of the HPA axis. However, in the case of bilateral adrenalectomy where there is no chance of endogenous cortisol production, prednisone may be prescribed by some providers, although this is not routine. A multidisciplinary approach with input from an endocrinologist should be used on discharge, and patients should be provided information about signs of cortisol withdrawal and adrenal insufficiency or crisis and what to do. Electrolyte levels, blood pressure, and glucose levels should be monitored after discharge. A transition of care from the surgeon to the endocrinologist and primary care physician should occur in a few weeks. Good communication with all health care professionals involved is key to the safety of the patient. Patients should be encouraged to obtain some sort of medical alert bracelet or chain to reflect that adrenalectomy has been performed and that corticosteroids may be lifesaving. This information can also be entered into smartphone emergency contacts which are accessible to rescue crews and other medical personnel.

Nelson Syndrome

Hypertrophy of the pituitary gland may develop after bilateral adrenalectomy.[114] Dependent on the degree of growth, this may result in headaches, vision impairment, and the cessation of menstrual periods in women. ACTH and β-melanocyte–stimulating hormone are elevated. This phenomenon occurs in an estimated 20% (range 0%–47%) of patients undergoing bilateral adrenalectomy.[114] Adenomas of the pituitary may develop, in addition to gland hypertrophy and hyperplasia. These are treated with medication, radiation, and/or surgery.

KEY POINTS

- Goals of care of patients undergoing adrenalectomy can be addressed according to the specific disease, type of hormone excess, and phase of care, including preoperative, intraoperative, postoperative and postdischarge phases.

Additional Considerations

Adrenalectomy in Pregnancy. As with other diagnoses necessitating surgery during pregnancy, it is best if adrenalectomy is delayed until after delivery.[115] Should surgery be required, it is best performed during the second trimester. Most commonly, adrenal disorders encountered during pregnancy include pheochromocytoma, Cushing syndrome, and adrenal cortical carcinoma, all of which are extremely rare. For those with Cushing syndrome, the scant amount of literature available suggests adrenalectomy during the second trimester.[116] While surgery can be pursued during the second trimester for pregnant patients with pheochromocytoma, it is likely best to wait until delivery or afterward and instead manage the patient with good alpha, beta, and/or calcium channel blockade. To maintain adequate placental perfusion pressure, maternal systolic pressure should be maintained at or above 120 mm Hg. Should resection of a pheochromocytoma be pursued during pregnancy, surgical, anesthesia, obstetric, and neonatal teams should work closely together throughout the pregnancy, and especially when surgery is pursued. If gestation is less than 32 weeks, where the fetus will not be delivered, the multidisciplinary team must aggressively treat hypertensive episodes while maintaining placental perfusion pressure. Aggressive volume repletion should be pursued before and during surgery to limit significant hypotension and decreased placental perfusion once the adrenal vein is ligated, along with any other venous outflow. Additional treatment with pressors is warranted if inadequate placental perfusion is questioned. If gestation is greater than 32 weeks, C-section can be performed, with adrenalectomy performed immediately afterward. Evaluating and managing patients with indeterminate adrenal masses where ACC is in the differential, or in those with confirmed ACC, is complicated. The full spectrum of diagnostic studies is not available. Hormones associated with pregnancy can obscure the biochemical evaluation. The common recommendations regarding surgery during pregnancy remain so for ACC during pregnancy. Should significant growth be noted during pregnancy, or if hormone excess is unable to be well controlled, which would compromise the safety of the mother or fetus, surgery during the second trimester may be pursued. Should surgery become more urgent during the third trimester, waiting until at least 32 weeks' gestation is best to allow for production of fetal pulmonary surfactant and greater maturation of the fetal lungs.

Adrenalectomy in the Pediatric Population. The pediatric population sees a different spectrum of adrenal disease than the adult population. Most adrenal disease in pediatric patients is the result of genetic mutations causing dysfunction or neoplasia. The incidence is rare, and the need for adrenalectomy is variable, depending on the disease process. Most often, disorders of adrenal function are recognized in the setting of precocious puberty, ambiguous sex, or change in secondary sexual characteristics. Adrenocortical carcinoma has two peaks in presentation: one in childhood and the other in the fifth and sixth decades of life. Adrenalectomy in children is similar in technique to that in adults. Open and minimally invasive approaches, including anterior and posterior, may be utilized. Use of computer-aided assistance is difficult in children, given the limited working space and resulting collision of the arms of the robot. In older children, it may be more feasible. Timing of and extent of adrenalectomy when performed for benign disease should be carefully considered, and especially when bilateral adrenalectomy is necessary. Balancing the risk of persistent hormone or catecholamine excess should be balanced against the risk of need for lifelong steroid replacement. Compliance should be factored into the decision as well. Partial adrenalectomy, with consideration for the technical aspects of any future surgery, can provide a reasonable alternative in many patients, again dependent on the disease process being treated.

Considerations in Resource-Limited Settings. Third- world, developing, and other resource-limited countries see a different distribution of adrenal disorders compared with more developed countries. Patient presentation and methods for evaluation can be quite different. Access to surgeons familiar with adrenal disorders and hospitals with resources to carry out minimally invasive approaches to adrenalectomy may be limited due to lack of access to adequate imaging, laboratory, and other ancillary resources, laparoscopic and other operating room equipment or mentorship and training to be able to perform minimally invasive adrenalectomy. Organizations such as the World Health Organization, universities with international alliances, surgical organizations, and private organizations can provide mentorship and assist with education in new procedures. Patient presentation, methods for evaluation, and disease processes encountered in these regions may be quite different from those in more developed nations. In a study from India,[117] a developing region with fewer resources than some, but more compared with many countries, ultrasound was the most commonly utilized imaging modality (69.4%), as CT and MRI (20.3%) were not widely available. The mean tumor size was significantly larger than in Western countries. Aldosterone and renin levels, routinely available in developed countries, were rarely measured due to financial constraints. Inflammatory lesions accounted for 9% of presenting adrenal disorders, something not often seen in more developed nations.

CONCLUSION

There have been significant changes in adrenalectomy over the past 120 years. Multiple approaches exist, technology has advanced, and outcomes have improved; yet, many of the original approaches remain relevant today. Each approach has unique advantages and disadvantages compared with other approaches. Surgeons performing adrenalectomy need to be well-versed in both the medical and surgical aspects of adrenal disorders to provide optimal care to patients. In the future, continued efforts to understand the biology of adrenal hormones will change the surgical approach to patients. Exciting discoveries in patients with dysregulation of aldosterone and cortisol production will drive new indications for surgery and refine and/or remove surgery as the treatment of choice in others. Advances in understanding malignant adrenal disorders, coupled with new medical therapies, will allow for refinement of surgical approaches in these patients, too.

KEY POINTS

- A thorough understanding of relevant adrenal anatomy, physiology, and interpretation of radiologic findings is critical to facilitate sound decision-making regarding adrenalectomy.
- The surgical approach to adrenalectomy should be chosen carefully and customized to the individual patient, taking into consideration the specific disease process and type of hormone excess, radiologic findings, concern for malignancy, patient anatomy, and comorbidities.
- Goals of care for patients undergoing adrenalectomy can be addressed according to the specific disease, type of hormone excess, and phase of care, including preoperative, intraoperative, postoperative, and postdischarge phases.
- Surgeons need to ensure performance of the critical elements of resection for adrenocortical carcinoma, with surgery best carried out in high-volume centers, given that surgery for benign adrenal disorders is quite different than that for adrenocortical carcinoma.

INTRODUCTION TO SEXUAL DEVELOPMENT

One of the most defining moments of our lives is when, in the womb, we embark on a male, female, or intermediate path. Variations of typical male or female development result in differences of sex development (DSDs), also referred to as intersex conditions. They occur frequently, in approximately 1% of the human population. DSDs are phenotypically heterogeneous, ranging from minor genital malformations (hypospadias, cryptorchidism, hypertrophy of the clitoris) to genital ambiguity. DSD can result in adverse consequences for mental health, fertility, cancer risk, and quality of life. For families, the birth of a child with a DSD, and the accompanying uncertainty about future psychological and sexual development, is believed to be extraordinarily stressful.

Recently, the debate over clinical management of DSD, in particular gender assignment and genital surgery, has intensified; yet the scientific data on patient outcomes have remained very incomplete. Major obstacles to optimal clinical management of DSD include gaps in understanding of pathophysiology, which impedes precise diagnostic categorization, along with the absence of prospective longitudinal studies of health and quality-of-life outcomes. Understanding the underlying mechanisms of sexual development is therefore crucial to the management of DSD. This chapter explores the embryological, genetic, and endocrine pathways underlying sexual development and their variations leading to DSD.

EMBRYOLOGY

Development of the gonads and genitalia comprises two major phases and has a sexually dimorphic timetable. In the earliest stages of gestation, the bipotential gonads develop into either ovaries or testes (sex determination). Testicular development is completed by approximately 8 weeks' gestation, but ovarian development does not begin until around 10 to 11 weeks' gestation. Development of these reproductive primordia during the first 6 weeks of human gestation is dependent on a network of interacting factors encoded by many genes. In the second stage, sex differentiation, two sets of undifferentiated embryonic internal and external genitalia develop along male or female lines, depending upon the nature of the hormonal secretions from the gonads and tissue responsiveness to those hormones. These processes occur between 8 and 14 weeks' gestation in the male fetus and extend into the middle of the second trimester in the female fetus. Each developmental phase is described separately in the sections that follow.

Gonadal Development (Sex Determination)

From a Bipotential Gonad to a Testis or an Ovary. The bipotential gonads hold a unique place in fetal development as the only organs that can pursue a dual developmental course into either a testis or an ovary. Each cell type within the bipotential gonad exhibits this dual potential, and as such an expression pattern is orchestrated within each cell type to promote the predetermined phenotype and actively repress the alternative pathway.[1,2] In the first few weeks of embryonic development, there are no discernable differences between the gonads and genitalia of 46,XY and 46,XX embryos. The renal, adrenal, and gonadal cell precursors all arise from the same regions of the primitive mesoderm and coelomic epithelium known as the adrenogenital primordium.[3] This region condenses to form a ridge on the dorsal wall of the body cavity, often referred to as the *urogenital ridge*. The most medial aspect of this urogenital ridge is the gonadal primordium (Fig. 101.1).[4]

As development progresses, the primary processes focus on cellular proliferation, and the transcriptional program required for this intense increase in cellular mass is shared by the adrenogenital primordium. Concurrently, between the fifth and sixth weeks of gestation (mouse

Figure 101.1 **A,** Embryology of the gonads. *1–2,* Primordial germ cells are located in the wall of the yolk sac in early embryogenesis. *3,* At about the fifth to sixth week of human gestation, germ cells migrate by ameboid movement from the coelomic epithelium, along the dorsal mesentery of the hindgut, to the genital ridge, the site of the future gonad. During formation of the indifferent (bipotential) gonad, the primordial germ cells infiltrate the primary sex cords, which subsequently become the seminiferous tubules of the testis or the primordial follicles of the ovary. *4–5,* Formation of the testis continues after arrival of the germ cells, although these are not required for the process to occur. Probably under the direction of the newly differentiated Sertoli cells, the primitive sex cords differentiate as the seminiferous tubules, in which germ cells are embedded. Morphologic development of the testis is complete by 8 weeks' gestation. Formation of the ovary occurs later than that of the testis, at around week 10 of human gestation, and requires the presence of germ cells. The primary sex cords develop into primordial follicles at approximately week 16 of gestation. **B,** Anatomic relationships between renal and gonadal primordia during embryogenesis. *Left*, Diagram of human fetus at 5 to 6 weeks' gestation. The primordial genital ridges are located just medial to the mesonephros, the primitive fetal kidney. The mesonephros is functional only during early fetal life and is replaced later in gestation by the metanephros (located more caudally in this diagram), which becomes the definitive kidney. The mesonephric duct, which later becomes the Wolffian duct, runs in a craniocaudal direction just lateral to the mesonephros. The paramesonephric duct, which later becomes the Müllerian duct, runs almost parallel to the mesonephric duct, a little farther laterally on the posterior abdominal wall. *Right*, Partial horizontal section of the fetus at 5 to 6 weeks' gestation, showing (from medial to lateral) the primitive sex cords (containing primordial germ cells), primitive kidney, mesonephric duct, and paramesonephric duct.

embryonic day [E]10.5–12), primordial germ cells migrate by ameboid movement from the endoderm of the yolk sac along the dorsal mesentery of the hindgut and into the bipotential gonad, where they invade the developing primary sex cords. At this stage, the gonad comprises an outer cortex and inner medulla, and there is still no morphologic difference between the gonads of male and female fetuses. Following the arrival of germ cells, the gonad begins to differentiate. As development progresses and populations of cells begin to differentiate along specific paths, there is a requirement for a much more focused and precise program of transcription-factor action, which must be actively maintained.[1,2] Despite the earlier belief that once sex determination occurred it was fixed, recent studies in mice have shown that the determination of cell fate within the developing gonad is reversible, and active repression of the alternate pathway is required throughout life.[1,2] However, whether this is true in humans has not been ascertained. In addition to cell types, several other aspects of gonadal development are sexually dimorphic, including blood vessel growth and the initiating factors that push the bipotential gonad toward development as a testis or an ovary.

Development of the Testis. The first discernible event in testis development is the appearance of primordial Sertoli cells, which differentiate from somatic cells of the coelomic epithelium at approximately 7 weeks of human gestation. Soon after their appearance in the gonadal ridge, Sertoli cells proliferate, aggregate around the primitive germ cells, and align into cordlike structures that subsequently become the seminiferous tubules (see Fig. 101.1).[4-6] The seclusion of germ cells within the tubules prevents meiosis and commits the germ cells to spermatogenic development. The prevention of meiosis may be a key event that directs gonadal development away from the ovarian pathway, as it is believed that testis cord formation and germ cell entry into meiosis are competing pathways in gonad development.

Another key event in testis development is the differentiation of peritubular myoid cells—smooth muscle-like cells that ensheath the testis cords to provide structural integrity—thought to derive from the same interstitial cell lineage as Leydig cells. These myoepithelial cells are required for the development of the testis cords, the defining event in testicular organogenesis.[7] Approximately 1 week after Sertoli cell development (around 8 weeks in human embryos), steroidogenic Leydig cells differentiate from primitive interstitial cells of mesonephric origin. This process may be controlled by paracrine influences from Sertoli cells, possibly anti-Müllerian hormone (AMH). Germ cells are not required for the processes of testis development to occur; morphologic testis development occurs in their absence.

Finally, establishment of testis-specific vasculature enables testicular hormones to be transported to the developing fetal internal and external genitalia to direct masculinization. Initially, the primitive vasculature of the genital ridge is similar in XX and XY gonads, until E11.5 in the mouse (approximately equivalent to 6 weeks of gestational age in humans). Between E11.5 and E12.5, XY gonads establish a pattern of blood flow distinct from that of XX gonads, with the development of a large male-specific coelomic vessel and a network of finely branched vessels.[8] Recruitment of vascular cells from the mesonephros is essential for the development of seminiferous tubules[9-11] and does not occur in XX gonads. The process of blood vessel development in the gonads is highly sexually dimorphic. The female gonad recruits vasculature by a classic angiogenic process. However, in the developing testis, vasculature is patterned by a remodeling mechanism that begins with the breakdown of an existing mesonephric vessel, followed by the migration and the reaggregation of XY endothelial cells to form the coelomic vessel.[12] The growth rate of the vasculature is similar between XX and XY gonads, but XY gonads show a distinct arterial specification during early testis development, as demonstrated by the male-specific pattern of gonadal expression of ephrin-B2, a marker of developing arteries.[13]

During the second trimester of human gestation, testicular volume increases exponentially, fueled primarily by doubling of Sertoli cell numbers every 2 weeks throughout this period. This rapid increase in Sertoli cells is accompanied by a parallel increase in germ cell number and an increase in Leydig cells.[7]

Development of the Ovary. In contrast with the testes, normal ovarian differentiation requires the presence of germ cells.[14,15] Without germ-cell seeding of the gonadal primordium, the tissue degenerates into a nonfunctional, mainly fibrous, “streak.” While the process of testis formation is complete by 8 weeks’ gestation, the process of ovarian development has not yet begun.[16] Only after 6 to 8 weeks of human gestation does ovarian structure begin to become distinguishable, with the development of the primary medullary sex cords. Secondary cortical sex cords provide the supporting structure for the germ cells arriving from the gut. Within the sex cords, the primary germ cells undergo vigorous mitotic replication to become oogonia; then the sex cords break up into clusters, becoming the primordial follicles at approximately week 16. The primordial follicles contain the diploid (i.e., 46 chromosomes) primary oocytes, which, after entering into the first stage of meiosis (reduction division), remain quiescent until puberty. Follicular (granulosa) cells arise from the same somatic cell lineage as Sertoli cells, and theca cells represent the ovarian counterpart of Leydig cells. The fact that female genital development is normal even in the absence of the ovary highlights the lack of involvement of the ovary in the processes of normal female sex differentiation. The embryologic development of the testis and ovary are summarized in Fig. 101.1.

In the 46,XX fetus, the cortex develops under the influence of the germ cell lineage, and the medulla regresses; in the 46,XY fetus, the reverse occurs, with development of the medullary sex cords under the influence of the supporting cell (pre-Sertoli) lineage (see Fig. 101.1).[17] The sexually dimorphic development of germ cells is dictated in large part by retinoid signaling.[18] The mesonephros produces large amounts of retinoic acid. In the developing male gonad, the cytochrome p450 enzyme Cyp26b1, which is expressed in somatic cells, degrades retinoids, and the primordial germ cells undergo mitotic arrest until later in development when they resume proliferation. In contrast, the developing female gonad does not express Cyp26b1, allowing retinoids to induce a genetic program (i.e., stimulated by retinoid acid 8) that results in germ cell entry into meiosis, where they arrest in meiosis I until stimulated to resume meiosis during follicle development in the adolescent and adult.

Development of Internal and External Genitalia (Sex Differentiation)

Male Sex Differentiation. Both the urinary and genital components of the urogenital duct systems are derived primarily from the intermediate mesoderm, which becomes segmented into units termed *nephrotomes.* By approximately week 4 of human gestation, the lateral portions of the nephrotomes unite, forming the mesonephric duct (later to become the Wolffian duct). At approximately 6 weeks’ gestation, the paramesonephric duct (forbear of the Müllerian duct) forms by invagination of a tube from the epithelium on the surface of the urogenital ridge, and by 6 weeks’ gestation, both male and female fetuses are endowed with two sets of internal reproductive duct structures[4,19] (see Figs. 101.1B and 101.3).

At week 4 of gestation, the external genitalia of both sexes are represented simply by a midline protuberance—the genital tubercle. By week 6, two medial folds—the urethral folds—flank the urogenital groove, and two larger folds—the labioscrotal folds—are present

laterally[19,20] (see Fig. 101.2). Subsequent sex-specific development is described in the sections that follow.

Once function of the testis is established at approximately 8 weeks of human gestation, development of the male sexual phenotype is under control of testicular secretions and the receptors that mediate their action. These include fetal luteinizing hormone (LH), the LH/chorionic gonadotropin (CG) receptor (LHCGR), at least five steroidogenic enzymes involved in testosterone biosynthesis, steroid 5α-reductase 2, required for conversion of testosterone to dihydrotestosterone (DHT), the androgen receptor (AR), AMH, and the AMH receptor.

From 8 weeks' gestation, hormonal secretions from the fetal testes induce masculinization of the internal genital structures.[19,21] Development of Wolffian structures requires testosterone, which is produced by testicular Leydig cells following activation of the cell surface LHCGR. Between 9 and 13 weeks' gestation, they undergo differentiation into the epididymides, vasa deferentia, and seminal vesicles. During the first trimester of gestation, the ligand for this receptor is probably CG, produced in large quantity by the placenta. Subsequently, endogenous fetal LH is the primary ligand. The lack of dependence upon fetal LH during genital morphogenesis is evidenced by the normal penile development of male infants with hypopituitarism; however, the subnormal penile size of these infants highlights the role of LH/testosterone action in the penile growth that normally occurs in the third trimester. Action of CG or LH at the Leydig cell LHCGR stimulates testicular steroidogenesis. Sertoli cells may also help regulate Leydig cell secretion in a paracrine fashion. The biochemistry and molecular biology of the steroidogenic enzymes is described in further detail later. The outcome of this multistep process is a high local (and to a lesser extent, systemic) concentration of testosterone. DHT does not appear to mediate the processes of Wolffian duct development, as the enzyme required for its production (5α-reductase 2) is not expressed in Wolffian tissues at the time of their differentiation.

In parallel to the masculinization of the internal genitalia represented by Wolffian development, a process of "defeminization" of the alternate set of genital ducts occurs as the Müllerian ducts regress under the influence of the locally acting glycoprotein hormone, AMH, secreted by testicular Sertoli cells, acting via a complex of serine/threonine kinase receptors. Action of AMH at its receptor results in involution of Müllerian structures by apoptosis. The Müllerian ducts are obliterated by week 11 of gestation, the only remnant of their existence in the 46,XY fetus being the prostatic utricle. Absence of one testis results in retention of the ipsilateral Müllerian structures and only limited Wolffian development on that side, indicating that the effects of AMH and testosterone on the internal genitalia are mediated largely in a paracrine fashion[16] (see Fig. 101.3).

Meanwhile, under the influence of androgen action (primarily the 5α-reduced derivative of testosterone, DHT), the genital tubercle elongates to form the body of the penis, and the urethral folds fuse ventrally from behind forward to form the penile urethra.[16,19,20] The labioscrotal swellings/folds grow toward each other, fusing in the midline to form the scrotum (see Fig. 101.2). DHT also induces the urogenital sinus to differentiate as the prostate and inhibits the formation of the vesicovaginal septum (described in the section entitled "Sex Differentiation"). These processes are completed by week 12 of gestation. Testosterone and DHT action are mediated by the AR, a

Figure 101.3 **Embryologic development of the internal genitalia.** *Top,* Indifferent stage. The primitive internal genitalia at 7 weeks' gestation have both paramesonephric or Müllerian (female) and mesonephric or Wolffian (male) duct systems. *Lower left,* Female development. In the 9- to 13-week female fetus, the Wolffian ducts regress *(dotted lines)*, and Müllerian ducts *(shaded)* differentiate and develop. Upper portions of Müllerian ducts form fallopian tubes; lower portions fuse to form the uterus, cervix, and upper part of the vagina. The urogenital sinus remains patent in the absence of androgen action, forming the lower part of the vagina. *Lower right,* Male development. Differentiation of the Wolffian ducts in the male fetus occurs under the influence of testosterone between 8 and 13 weeks' gestation. These develop as the epididymides, vasa deferentia, and seminal vesicles *(shaded)*. By week 11, Müllerian ducts *(dotted lines)* are obliterated by a process of apoptosis that occurs under the direction of anti-Müllerian hormone (AMH) secreted by Sertoli cells.

nuclear receptor/transcription factor found in high concentration in the tissues of the Wolffian ducts and external genitalia (where DHT is the ligand). In the absence of high androgen concentration, as in the female (or androgen-deficient) fetus, there is insufficient activated AR to induce transcription of target genes required for stabilization and development of the Wolffian system and for masculinization of the external genitalia.

Between 12 and 24 weeks' gestation, the testes migrate from their original lumbar location to the level of the internal inguinal ring above the scrotum. Descent of the testes through the inguinal ring and into the scrotum, controlled by testosterone, begins around week 28, and in most infants is completed by term. Testicular descent is also controlled by a Leydig cell–secreted protein, insulin-like protein 3, which belongs to the insulin-like hormone superfamily (including insulin, relaxin, and insulin-like growth factors 1 and 2).

Female Sex Differentiation. In the absence of testicular secretions, as in the 46,XX fetus, a set of genital tract developmental processes inverse to those described for the male occurs.[20,21] The Wolffian ducts regress, a phenomenon long thought to be caused by the absence of androgen, but recently shown to be actively promoted by COUP-TFII, suppressing mesenchyme-epithelium crosstalk responsible for

Wolffian duct maintenance.[22] In the absence of AMH, the Müllerian ducts are permitted to develop. Their upper portions form the fallopian tubes; the lower sections fuse and differentiate as the uterus and upper part of the vagina (see Fig. 101.3). The lower portion of the vagina derives from the urogenital sinus (the ventral part of the embryonic mammalian cloaca formed by the growth of a fold dividing the cloaca where the gut and allantois meet), which remains patent when not exposed to androgen. External genital development in the female fetus (or androgen-deficient or resistant male) begins with the elongation of the genital tubercle to form the clitoris, and the urogenital sinus remains open (see Fig. 101.2). The vesicovaginal septum (a fold of tissue that develops in the female to separate the posterior wall of the bladder from the anterior wall of the vagina) forms, so that the urethra opens anteriorly and the vagina posteriorly.[16,19,20] The vestibule of the urogenital sinus is bordered laterally by the urethral folds, which do not fuse and instead develop as the labia minora. Further lateral, the labioscrotal swellings enlarge somewhat but also remain unfused, forming the labia majora. There is minor labial fusion posteriorly, forming the posterior commissure, and anteriorly, producing the mons pubis. These events occur from about week 7 to week 12 of gestation.

KEY POINTS

- Sex determination is the initial developmental choice leading to testis or ovary from the undifferentiated, bipotential gonad. Sex differentiation refers to the steps subsequent to sex determination, including the development of the internal and external genitalia.

GENETIC PATHWAYS OF SEX DEVELOPMENT AND THEIR VARIATIONS

Genetic Pathways

The strategy of sexual development is divided into two sequential stages: sex determination and sex differentiation (Fig. 101.4). Sex determination starts with the sex chromosome complement, inherited from the parental gametes, which in turn prompts a path of molecular signaling events in the presence or absence of the Y chromosome, driving the bipotential gonad in the developing embryo towards a male or female fate, respectively. Expression of Y-linked gene *SRY* in the somatic cells of the bipotential gonad of an XY embryo kickstarts a cascade of signaling events that lead to testicular organogenesis. In the absence of *SRY*, female-specific pathways are initiated, triggering ovarian development under the control of genes such as *RSPO1, WNT4*, and *DAX1/NR0B1*.

Sex differentiation follows the development of a testis or an ovary from a bipotential gonad. Under the influence of hormones and signaling molecules secreted by the testicular or ovarian tissues, sex-specific morphogenesis of the reproductive organs (external and internal) occurs and is named sex differentiation. Disruption of these developmental processes and of the enzymatic cascades involved in the synthesis of steroid hormones in the adrenals and gonads, as well as in the central control of these processes, can lead to DSD. The molecular mechanisms involved in this pathways have been reviewed in detail in numerous publications.[23-27] We will focus on the clinical applications of the variations of genetic pathways.

Genetic Variants Associated with Differences of Sex Development

A major issue to the understanding of the role of genes in DSD is to make sense of the immense number of variants identified in genes involved in sexual development. Some of them will be frequent in the general population and therefore likely benign, while others will be rarer and more likely to be pathogenic. We have summarized, in Table 101.1, the variants reported in ClinVar, the repository of clinical genomic variation curated by the National Institutes of Health. Sixty-nine genes associated with a DSD phenotype are presented (commonly present in diagnostic panels). For each gene, the type of variant (missense, nonsense, frameshift, larger INDELs, and rearrangements) is reported.

KEY POINTS

- A complex network of genetic pathways contributes to sexual development. Variations in the genes involved in sex determination and sex differentiation contribute to variations in the phenotypes of the gonads and genitalia.

DIFFERENCES OF SEX DEVELOPMENT

The term DSD, defined as "congenital conditions in which development of chromosomal, gonadal, or anatomical sex is atypical,"[28,29] was adopted following the 2005 consensus meeting of the Lawson Wilkins Pediatric Endocrine Society and the European Society for Paediatric Endocrinology. It replaces controversial terms such as hermaphroditism, pseudohermaphroditism, and intersex. This umbrella term covers a wide variety of phenotypes (e.g., hypospadias, discordance between external genitalia and chromosomal sex); hormonal phenotypes (e.g., androgen insensitivity, over-/undersecretion of androgens); gonadal phenotypes (e.g., gonadal dysgenesis, ovotestis); and chromosomal complements (e.g., 46,XY, 46,XX, 47,XXY, 45,X). DSD can occur in isolated or syndromic forms, which are presented in Table 101.2 and reviewed elsewhere.[30,31] There has been considerable debate about the word "disorder" within DSD, with positive aspects described in the Global DSD Update,[32] such as simplified access to insurance coverage and a clearer distinction from conditions such as gender dysphoria, but also negative connotations such as stigma often accompanying the word "disorder." For this chapter and, recognizing the negative social impact of the word "disorder," we have elected to replace it with the word "difference," which has been increasingly used in the literature and by advocacy organizations, and which does not modify the well-recognized acronym DSD.

The classification of DSD is based on the physiopathology and categorized by karyotype as 46,XX DSD, 46,XY DSD, and sex chromosome DSD (Table 101.3).

46,XX Differences of Sex Development

DSD in 46,XX individuals can be broadly categorized as 1) differences of gonadal development (including 46,XX testicular DSD, 46,XX ovotesticular DSD, and 46,XX pure gonadal dysgenesis), 2) 46,XX DSD due to androgen excess (resulting from virilizing congenital adrenal hyperplasias [CAHs], maternal-derived androgens, and aromatase

TABLE 101.2 Syndromic Forms of Differences of Sex Development (DSD)

Syndromes Associated with Differences of Sex Development	Mutated Gene	Phenotype	OMIM
46,XY DSD with congenital heart defect	*GATA4*		615542
Aarskog syndrome	*FGD1*	Short stature, facial dysmorphism, brachydactyly. Scrotal anomalies in XY	305400
Axenfeld–Rieger type 1	PITX2	Hypospadias	180500
Bardet–Biedl syndrome (AR, oligogenic?)	20+ loci	Retinitis pigmentosa, obesity, intellectual disability, renal anomalies, polydactyly, genital anomalies	209900
Blepharophimosis-ptosis-epicanthus inversus syndrome type 1 (AD, AR)	*FOXL2*	With or without premature ovarian failure	110100
Borjeson–Forssman–Lehmann syndrome	Unknown	Severe mental defects, epilepsy, hypogonadism, hypometabolism, marked obesity	301900
Campomelic dysplasia	*SOX9*	Ambiguous genitalia, congenital bowing of long bones, hypoplastic scapulae, thoracic vertebrae pedicles. Sex reversal in XY	114290
CHARGE syndrome (AD)	*CHD7*	Choanal atresia, intellectual disability; inner ear, retinal, and genital abnormalities in XX and XY	214800
Cornelia de Lange syndrome	*NIPBL*	Low anterior hairline, anteverted nares, maxillary prognathism, long philtrum, "carp" mouth in association with prenatal and postnatal growth restriction, intellectual disability. Genital anomalies in XY	122470
Cystic fibrosis	*CFTR*	Congenital absence of vasa deferentia	277180
Denys–Drash syndrome	*WT1*	Early diffuse mesangial sclerosis of kidneys, Wilms' tumor. Genital and gonadal anomalies in XX and XY	194080
DSD with adrenal hypoplasia XY GD	*NR5A1/SF1*	Hypoplasia, XY gonadal dysgenesis	300200
Dubowitz syndrome	Unknown	Short stature, microcephaly, mild intellectual disability with behavior problems, eczema, distinctive facies	223370
Faciogenitopopliteal syndrome	Unknown	Cleft palate, webbing of the intercural pterygium	119500
Frasier syndrome	*WT1*	XY and XY gonadal dysgenesis, early adolescent progressive glomerulopathy, gonadoblastoma	136680
Genitourinary and/or brain malformation syndrome (GUBS) (AD)	*PPP1R12A* (*de novo*)	Seizures, holoprosencephaly, genital anomalies in XY	602021
Goldenhar syndrome (hemifacial microsomia)	Unknown	Unilateral deformity of the external ear and small ipsilateral half of the face, with epibulbar dermoid, vertebral anomalies, and congenital cardiac anomalies	164210
Gonadal dysgenesis with neuropathy	*DHH*	XY GD with associated minifascicular neuropathy (one of four cases)	607080
Hand-Foot-Genital Syndrome	*HOXA13*	Carpal, tarsal, digit anomalies, Müllerian fusion in XX, hypospadias in XY	140000
Holoproscencephaly	Many	Craniofacial dysmorphology	236100
Hyperterlorism with esophageal abnormality and hypospadias	Unknown	Laryngotracheoesophageal cleft; clefts of lip, palate, and uvula; difficulty swallowing, hoarse cry; genitourinary defects, intellectual disability; congenital heart defects	145410
IMAGe syndrome	*CDKN1C* (imprinted)	Intrauterine growth restriction, metaphyseal dysplasia, adrenal hypoplasia congenita, genital anomalies	614732

TABLE 101.2 Syndromic Forms of Differences of Sex Development (DSD)—cont'd

Syndromes Associated with Differences of Sex Development	Mutated Gene	Phenotype	OMIM
Johanson–Blizzard syndrome	Unknown	Aplasia or hypoplasia of the nasal alae, congenital deafness, hypothyroidism, postnatal growth delay, malabsorption, intellectual disability, midline ectodermal scalp defects, absent permanent teeth	243800
Juberg–Marsidi Syndrome	Unknown	Cleft lip/palate, with abnormal thumbs and microcephaly	216100
Kallmann syndrome	*FGFR-1,* oligogenic + 24 others	Hypogonadotropic hypogonadism and anosmia	308700
Lenz–Majewski hyperstosis syndrome	Unknown	High palate; short, yellow, carious teeth; progeroid appearance; short stature; increased venous pattern of the forehead and thorax	151050
Lowe syndrome (XLR)	*OCRL*	Hydrophtalmia, cataract, intellectual disability, vitamin D–resistant rickets, amino aciduria and cryptorchidism	309000
Malpeuch facial clefting syndrome	Unknown	Short stature, hypertelorism, eye anomalies, facial clefting, hearing loss, urogenital abnormalities, intellectual disabilities	248340
Maturity onset diabetes of the young type 5 (MODY-5)	*HNF1B* (also named *TCF-2*)	Müllerian aplasia and renal dysfunction	137920
McKusick–Kaufman syndrome	Unknown	Hydometrocolpos, congenital heart malformations, postaxial polydactyly	236700
Miller–Dieker Syndrome	17p13.3 deletion	Lissencephaly, growth restriction, intellectual disability, +/- heart, face, kidney anomalies. Genital anomalies in XY	247200
MURCS = Mayer–Rokitansky–Kuster–Hauser Syndrome (MRKH) with developmental anomalies (in XX)	*WNT4* (in subset of MRKH with hyperandrogenism)	Müllerian duct aplasia, renal agenesis, cervicothoracic somite anomalies, deafness.	277000
MURCS syndrome	Unknown	Müllerian duct aplasia, renal aplasia, cervicothoracic somite dysplasia	601076
Najjar syndrome	Unknown	Genital anomaly, intellectual disability, cardiomyopathy	212120
Noonan syndrome	*PTPN11*	Hypertelorism, downward eye slant, and low-set posteriorly rotated ears, short stature, webbed neck, cardiac anomalies. Cryptorchidism in XY	163950
Opitz G/BBB	*MID1*	Hypospadias	300000
Pallister–Hall Syndrome (AD)	*GLI3*	Hypothalamic hamartoblastoma, pituitary dysfunction, postaxial polydactyly, other developmental anomalies. Genital anomalies in XY	146510
Palmoplantar hyperkeratosis with squamous cell carcinoma and XX sex reversal (AR)	*RSPO1*	Congenital bilateral corneal opacities, onychodystrophy, and hearing impairment	610644
Prader–Willi Syndrome	*SNRPN*, chr. 15q11.2 imprinting	Obesity, muscular hypotonia, intellectual disability, short stature, hypogonadotropic hypogonadism in XY; hypoplastic labia, amenorrhea in XX	176270
Robinow syndrome	*ROR2*	Mesomelic limb shortening, facial dysmorphism. Genital anomalies in XX and XY	180700
Rubinstein-Taybi syndrome	*CREBBP*	Intellectual disability, broad thumbs and toes, facial abnormalities. Hypospadias, shawl scrotum in XY	180849
Seckel syndrome	*SCKL1*	Short stature, microcephaly with intellectual disability, characteristic "birdheaded" facial appearance. Hypospadias in XY, clitoromegaly in XX	210600
Smith–Lemil–Opitz syndrome (AR)	*DHCR7*	Multiple congenital malformations and intellectual disability, genital abnormalities in XY	270400
Torticollis, keloids, cryptochidism, renal dysplasia	Unknown	Torticollis, keloids, cryptochidism, renal dysplasia	314300
Ubiquitous glucose-6-phosphatase deficiency	*G6PC3*	Severe congenital neutropenia plus cardiovascular and/or urogenital abnormalities	611045
VACTERL/VACTER	Unknown	Vertebral defects, anal atresia, tracheoesophageal fistula with esophageal atresia, radial dysplasia, limb anomalies	192350
Varadi–Papp syndrome	Unknown	Big toes, hexadactyly, cleft lip/palate or lingual nodule, somatic and psychomotor disability; some show absent olfactory bulbs and tracts, cryptochidism	277170
Velocardiofacial	Del 22q11.2 (*TBX1*)	Hypospadias, Müllerian aplasia, and renal dysfunction	192430
X-linked alpha-thalassemia/intellectual disability	*ATRX*	Hemoglobin H disease, intellectual disability, dysmorphic facies, hypogonadism	301040

XLR, X-linked recessive; *AR*, autosomal recessive; *AD*, autosomal dominant.

TABLE 101.3 Classification of Differences in Sex Development (DSD)

Sex Chromosome DSD	46,XY DSD	46,XX DSD
45,X (Turner Syndrome and variants)	*Differences of gonadal (testicular) development* • complete gonadal dysgenesis (Swyer syndrome) • partial gonadal dysgenesis • gonadal regression • ovotesticular DSD	*Differences of gonadal (ovarian) development:* • ovotesticular DSD • testicular DSD (e.g., *SRY*$^+$, duplicate *SOX9*) • gonadal dysgenesis
47,XXY (Klinefelter syndrome and variants)	*Disorders in androgen synthesis or action* • androgen biosynthesis defect (e.g., 17β-hydroxysteroid dehydrogenase deficiency, 5αRD2 deficiency, StAR mutations) • defect in androgen action (e.g., complete androgen insensitivity syndrome, partial androgen insensitivity syndrome) • luteinizing hormone receptor defects (e.g., Leydig cell hypoplasia, aplasia)	*Androgen excess* • fetal (e.g., 21-hydroxylase deficiency, 11β-hydroxylase deficiency) • fetoplacental (aromatase deficiency, POR [P450 oxidoreductase]) • maternal (luteoma, exogenous, etc.)
45,X/46,XY (Mixed gonadal dysgenesis, ovotesticular DSD)	*Disorders of anti-Müllerian hormone and anti-Müllerian hormone receptor* (persistent Müllerian duct syndrome)	*Other* (e.g., cloacal exstrophy, vaginal atresia, MURCS [Müllerian, renal, cervicothoracic somite abnormalities], other syndromes)
46XX/46,XY (chimeric, ovotesticular DSD)	*Other* (e.g., complex syndromic disorders)	

deficiency), and 3) other (such as disorders of Müllerian development and syndromic disorders).

46,XX Differences in Gonadal Development

46,XX Testicular Differences of Sex Development. This condition, previously called XX male or XX sex reversal, is characterized by testicular development and complete virilization of the internal and external genitalia in subjects who have two X chromosomes and lack a Y chromosome. Approximately one in 20,000 to 30,000 males have a 46,XX karyotype. Most cases are sporadic, and a form of X-Y paternal interchange is suggested when part of the short arm of the Y chromosome carrying *SRY* is transferred to one of the two X chromosomes.

The high sequence identity and identical orientation of *PRKY* to its homologous gene on the X chromosome, *PRKX*, seem to explain the high frequency of abnormal pairing and subsequent ectopic recombination outside the pseudoautosomal region, leading to 46,XX males and 46,XY females (Fig. 101.5).[33] *SRY*(+) XX males usually have a normal male phenotype with no particular feature during childhood. A small proportion (~10%) of XX males lack *SRY* sequences. The underlying pathogenic mechanism has remained elusive for years, but the recent advent of high throughput genetic analyses has allowed the identification of familial forms of *SRY*(-) XX males associated with overexpression of *SOX3*, *SOX9*,[34–42] or *SOX10*[43] resulting from gene duplication. The interpretation should be cautious in *SRY*(-) 46,XX patients with ambiguous genitalia: insufficient sampling of the gonads may miss ovarian tissue.

Before puberty, testicular endocrine function does not seem to be affected in XX males.[44] The condition is often diagnosed at puberty or adulthood owing to small testes, gynecomastia, and sterility, associated with some degree of testosterone deficiency and elevated gonadotropins.[45]

Owing to the presence of two X chromosomes and the lack of Y chromosome genes involved in spermatogenesis, germ cells do not go through meiosis, which explains the small testis size and azoospermia, as is seen in Klinefelter syndrome. However, XX males show shorter stature than Klinefelter patients.[45,46]

Ovotesticular Differences of Sex Development. Ovotesticular (OT)-DSD, formerly known as "true hermaphroditism," a pejorative term that is no longer used but is still present in the older literature, is defined by the presence of both ovarian and testicular tissue in the same individual.

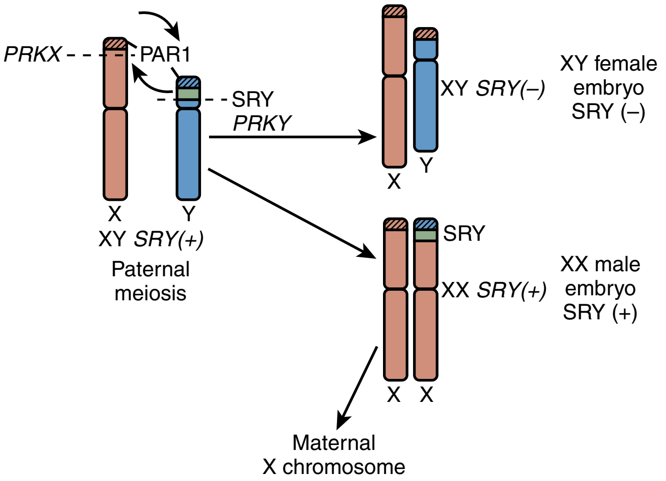

Figure 101.5 **Origin of *SRY*-negative XY females and *SRY*-positive XX males.** During meiosis in the paternal germ cells, an abnormal translocation occurs of *SRY* from the Y chromosome to the X chromosome (for example, at the level of the *PRKX* and *PRKY* genes). If the spermatozoon carrying an X chromosome with *SRY* fertilizes an oocyte, an *SRY*-positive XX embryo results. Conversely, if the spermatozoon carrying the *SRY*-negative Y chromosome fertilizes an oocyte, an *SRY*-negative XY embryo results.

The gonadal distribution of OT-DSD can be referred to as unilateral (ovotestis on one side and testis or ovary on the other), bilateral (ovotestis on each side), or lateral (testis on one side and ovary on the other).[47] The most common form is unilateral, with ovotestis/ovary in 34%, followed by bilateral (ovotestis/ovotestis) in 29% and lateral (ovary/testis) in 25%. The least frequent is unilateral with ovotestis/testis (12%).[48,49]

The degree of genital ambiguity depends on the mass of functional testicular tissue and may range from almost normal female to almost normal male appearance. In the absence of genital ambiguity, the diagnosis is reached at puberty because of virilization in patients reared as females, or gynecomastia and urethral bleeding in those raised male. Ovarian tissue is usually of good quality, and patients reared as females often experience normal pubertal development with menses[50]; pregnancy has been reported in a dozen cases, but only half have resulted in live births.[51] Testicular tissue progressively becomes dysgenetic. Two cases of spermatogenesis in males with OT-DSD have been reported.[48]

The geographical distribution of OT-DSD shows an overrepresentation in Africa, with the number of published cases at 17 per 100 million inhabitants, followed by Europe at 15.3. Asia is underrepresented, at 1.2 cases per 100 million, and South America at 3.6 per 100 million.[48]

The most frequent karyotype is 46,XX (65% of cases), and it is interesting to note that, in most cases, 46,XX patients do not carry the *SRY* gene,[52,53] and the cause remains unexplained genetically for the majority of them. Approximately 10% are XY, and the remaining are complex mosaics containing a Y chromosome.[48,49]

SRY translocated on one X explains approximately 10% of XX OT-DSD, and in some patients it is limited to gonadal mosaicism.[54] A small number of XY patients with OT-DSD carry point mutations in *SRY*.[55] It is likely that *SRY*(+) and *SRY*(-) OT-DSD and testicular DSD (T-DSD) are part of the same clinical spectrum, as OT-DSD and T-DSD can be observed in the same family, and with the same causative genotype, such as the presence of a translocated *SRY* gene.[56,57] The nonrandom inactivation of the *SRY*-bearing X chromosome has been proposed as an explanation for OT-DSD in *SRY*(+) XX OT-DSD.[58] The clinical features of OT-DSD are similar, whether or not the karyotype contains a Y chromosome, apart from the risk for gonadal tumors, which is higher if a Y chromosome is present.[59]

Recently, mutations in the *RSPO-1* gene have been identified in *SRY*(-) XX patients with OT-DSD associated with palmoplantar hyperkeratosis with squamous cell carcinoma of the skin.[60,61]

Partial 22q duplication (containing the *SOX10* gene) with OT-DSD (46,XX) has been described.[43] A case of a *de novo* heterozygous 3-Mb deletion on chromosome 15q26.2 has been reported in a 20-year-old with OT-DSD.[62] Duplication of the region of chromosome 17 containing *SOX9* has been identified as associated with OT-DSD, whether *SOX9* or a regulatory region upstream of *SOX9* is duplicated.[63-66]

There have been examples of specific point mutations in known sex-determining genes (*NR5A1*, encoding steroidogenic factor 1 [SF1], and Wilms' tumor 1 (*WT1*]) that typically cause XY gonadal dysgenesis associated with XX OT-DSD. The heterozygous missense mutation p.Arg92Trp in the part of *NR5A1* encoding an accessory DNA-binding region was found in cases of 46,XX OT-DSD.[67] This particular variant may switch the development pathway from ovarian to testicular tissue. Another example is heterozygous variants affecting the fourth zinc finger (ZF4) of the *WT1* gene. In a series of 78 patients with T-DSD and OT-DSD, all *SRY*(-), seven (approximately 9%) were found to have a variant in the ZF4 domain of WT1.[68] The occurrence of specific point mutations in *SRY*(-) OT-DSD suggests that a diagnostic approach including whole-exome sequencing is indicated.

46,XX Pure Gonadal Dysgenesis (Ovarian Dysgenesis). Ovarian dysgenesis can broadly be defined as conditions resulting from genetic defects in ovarian development, including impairment in early ovarian development (i.e., primordial follicle formation and differentiation) as well as defects in the later stages of follicle development at the time of puberty. Individuals with 46,XX pure gonadal dysgenesis are classically born with normal external female genitalia and diagnosed at puberty due primary amenorrhea, absent breast development, and elevated gonadotropins. It is important to distinguish ovarian dysgenesis from premature ovarian insufficiency (POI), an umbrella term encompassing a variety of conditions associated with impaired ovarian function, including ovarian dysgenesis (also see Chapter 122). Fifty to ninety percent of cases of POI have been historically been considered "idiopathic"; however, multiple candidate genes involved in ovarian development have been described in recent years, though not all have been confirmed in animal models.[69] X chromosome abnormalities (including Turner syndrome [TS], described later) are the most common genetic causes of POI. Premutations in the fragile X mental retardation 1 gene (*FMR1*), located on the long arm of the X chromosome at Xq27.3, have been associated with both sporadic and familial POI.[70] Haploinsufficiency of bone morphogenetic protein 15 (*BMP-15*) at Xp11.2 appears to cause X-linked ovarian dysgenesis in affected females, likely due to impairment of folliculogenesis.[71] Among autosomal genes, mutations in forkhead box L2 (*FOXL2*, encoding a factor essential for primary follicular development) are responsible for a syndromic cause of POI, blepharophimosis ptosis epicanthus inversus syndrome type 1, but have also been implicated in nonsyndromic POI.[72,73] POI has also been reported with mutations in the gene encoding PSMC3-interacting protein (PSMC3IP),[73] a nuclear protein involved in meiotic recombination and as a coactivator of estrogen-driven transcription, in NOBOX oogenesis homeobox (*NOBOX*),[74] an ovary-specific gene involved in signal transduction, and in stromal antigen 3 (*STAG3*),[75] a gene encoding a meiosis-specific subunit of the cohesin ring. Mutations in nuclear receptor subfamily 5 group A member 1 (*NR5A1*, also known as *SF1*), a modulator of ovarian steroidogenesis, have been identified in several cases of familial and idiopathic POI.[76] Mutations in the gonadotropin receptor,[77,78] estrogen receptor alpha,[79]and aromatase [80] genes impair ovarian function but do not appear to induce typical ovarian dysgenesis. POI also occurs in several genetic syndromes,[69] including ataxia telangiectasia, ovarian leukodystrophy, and Perrault syndrome (ovarian dysgenesis with deafness). However, in most cases of syndromic POI, it is unclear that POI has resulted from ovarian dysgenesis.

46,XX Differences of Sex Development due to Androgen Excess. Virilization of a 46,XX fetus occurs due to exposure to androgens in fetal development. Androgen excess causes clitoromegaly and fusion of the labioscrotal folds, leading the external genitalia to appear "ambiguous," or, in severe cases, completely male-appearing but without palpable testes (see Fig. 101.6A and B). The separation of urethra and vagina may also be disrupted, leading to a common urogenital sinus. DHT is the predominant androgen leading to labioscrotal fusion and clitorophallic growth. The degree of virilization depends both on the amount of exposure to DHT, as well as the time frame of exposure (labioscrotal fusion typically occurs when DHT is present before 12 weeks' gestational age, whereas clitorophallic growth may occur due to androgen exposure throughout gestation). The most common source of androgens leading to 46,XX virilization is the fetal adrenal, as a result of fetal virilizing CAH. Less common causes of 46,XX fetal virilization include aromatase deficiency and exposure to maternal-derived androgens.

Virilizing Congenital Adrenal Hyperplasias. CAH is a group of autosomal recessive disorders resulting from adrenal steroidogenic enzymatic deficiencies impacting cortisol production. Details of the incidence, molecular genetics, clinical presentation, and diagnosis of the forms CAH are discussed in detail in Chapter 94 but are briefly described here as well. Due to impaired cortisol synthesis, there is loss of negative feedback inhibition of the hypothalamic pituitary adrenal axis. The resultant increase in adrenocorticotropic hormone (ACTH) secretion overstimulates the adrenal cortex and drives accumulation of cortisol precursors (Fig. 101.7). In the virilizing forms of CAH, cortisol precursors are shunted towards adrenal androgens, leading to masculinization of external genitalia in 46,XX individuals. Affected females have normal ovarian development and, due to the absence of anti-Müllerian hormone, normal Müllerian duct development (Fig. 101.8). The degree of genital virilization in female infants with CAH is variable, ranging from mild clitoromegaly to male-appearing genitalia. Fusion of the labioscrotal

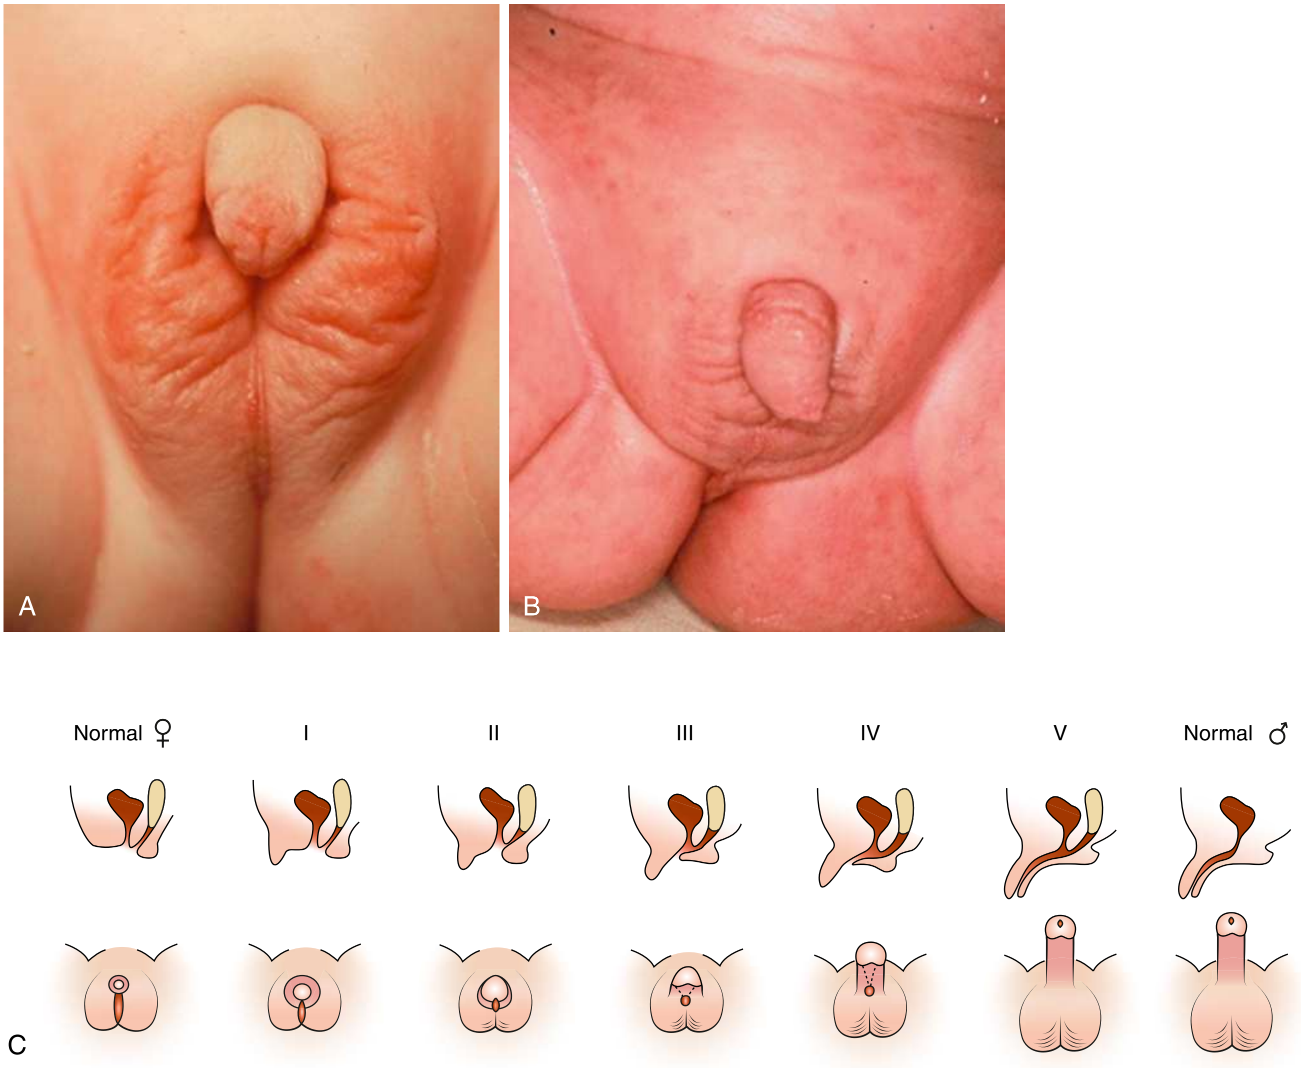

Figure 101.6 **Genitalia of 46,XX patients with congenital adrenal hyperplasia (CAH) resulting from 21-hydroxylase deficiency. A,** Prader stage 4. **B,** Prader stage 5. **C,** Schematic of Prader staging for patients with CAH. (**A** and **B** Kindly provided by Dr. M. Podestá, Buenos Aires. **C** Reprinted from Ogilvy-Stuart AL, Brain CE. Early assessment of ambiguous genitalia. *Arch Dis Child.* 2004;89;401–407, with permission from BMJ Publishing Group Ltd.)

folds may occur, leading to the appearance of male scrotum but without palpable testes. Internal lower urogenital anatomy may also be impacted, with the development of a common urogenital sinus comprising the confluence of the urethra and vagina. Rarely, there can be complete fusion of the labioscrotal folds resulting in a penis-like structure with normally positioned urethral meatus at the tip of the glans. Apart from elevated adrenal androgen precursors, other factors influencing the degree of genital virilization may include the degree of conversion of androgen precursors to more potent products (e.g., DHT) and the concentration and transcriptional activity of androgen receptors.[81]

The severity of virilization of the external genitalia in 46,XX females has typically been described using the five-point Prader scale (Fig. 101.6C); however, other validated tools exist. The degree of labioscrotal fusion can be described in newborn females via the measurement of anogenital distances (ratio of the measurement from the center of the anus to fourchette to the measurement from the center of the anus to the anterior base of the clitoris).[82] More recently, the External Genitalia Score (EGS) has been developed as a gradual scale ranging from female (EGS=0) to male (EGS=12), to be used in both sexes.[83] The EGS incorporates degree of labioscrotal fusion (Fig. 101.9), length of the genital tubercle, position of the urethral meatus, and location of the gonads.

Despite published evidence of masculine gender behaviors in females with CAH, the majority of female-raised individuals with 46,XX CAH report female core gender identity (with around 5% reporting gender dysphoria).[84] Optimal gender assignment in the rare patients with 46,XX CAH and complete virilization (Prader 5, with normally formed penis) is an area of controversy.[81]

21-Hydroxylase Deficiency. The most common cause of 46,XX DSD is a deficiency in 21-hydroxylase, an enzyme that is required for both cortisol and aldosterone production (see Fig. 101.7). As discussed in Chapter 94, classic forms of 21-hydroxylase deficiency (21-OHD) are associated with significantly reduced enzyme activity, leading to accumulation of the adrenal precursor 17-hydroxyprogesterone (17-OHP). Individuals with classic 21-OHD present in infancy with cortisol deficiency and, in salt-wasting forms, aldosterone deficiency. Affected females have genital ambiguity as a result of excess DHT produced from accumulated adrenal androgens (including the conversion of 17-OHP to DHT via the "backdoor" or "alternative" pathway) (see Fig. 101.10);

Figure 101.7 Adrenal and gonadal steroidogenesis. The first four steps take place in both adrenals and gonads *(yellow)*. (1) *StAR,* Steroidogenic acute regulatory protein; (2) *P450scc,* Cholesterol side-chain cleavage; (3) *3β-HSD,* 3β-Hydroxysteroid dehydrogenase type 2; (4) P450c17 for both 17α-hydroxylase and 17,20-lyase (or desmolase). Subsequent steps are organ-specific. In the adrenal cortex *(blue)* P450c21, 21-hydroxylase, and P450c11, 11β-hydroxylase, are active in both the zona glomerulosa and fasciculata. Then P450aldo (aldosterone synthase with its two activities, 18-hydroxylase and 18-dehydrogenase or oxidase) is specific of zona glomerulosa. In the gonads, 17β-HSD, for 17β-hydroxysteroid dehydrogenase type 3, synthesizes testosterone, and P450aro aromatizes androgens to estrogens. Mainly in peripheral androgen-target tissues, 5α-reductase converts testosterone to dihydrotestosterone (DHT). POR (P450 oxidoreductase) is a flavoprotein necessary for most P450 cytochromes.

however, affected males have normal genitalia and penile size. Prompt diagnosis and treatment are necessary to prevent adrenal crisis. Infants born with ambiguous or male-appearing genitalia and nonpalpable gonads should be immediately evaluated for 46,XX DSD due to classic 21-OHD by measurement of 17-OHP; markedly elevated levels greater than 10,000 ng/dL are suggestive of the diagnosis (Table 101.4). Because 17-OHP may not be unequivocally elevated the first day of life, hormonal investigations must be repeated daily unless an alternative diagnosis is found. Meanwhile, studies of salt balance (Na+, K+ in blood and urine) should also be performed, as salt loss usually appears evident from the end of the second week of life. Less severe defects in the 21-hydroxylase enzyme may result in nonclassic or "late-onset" 21-OHD; however, this disorder is generally milder, is associated with subclinical cortisol deficiencies and less severe androgen excess, and does not typically lead to genital ambiguity in female newborns. The 21-hydroxylase enzyme is encoded by the gene *CYP21A2* on chromosome 6 (6p21.3) in a region that includes a homologous pseudogene, *CYP21A1P*. Recombination events between *CYP21A12* and its pseudogene lead to mutant alleles with variable degree of enzymatic compromise (see Chapter 94).

11β-Hydroxylase Deficiency. 11β-hydroxylase deficiency is a less common form of virilizing CAH (see Chapter 94). The hormonal marker of the disorder is the selective elevation of 11-deoxycortisol due to impaired conversion to cortisol (see Table 101.4). Accumulation of another adrenal precursor, deoxycortisone (an active mineralocorticoid), leads to salt retention, hypokalemia, and hypertension. Due to absence of salt wasting, adrenal crisis is rare. Affected females with the severe or "classic" form of 11β-hydroxylase deficiency will exhibit masculinization of the external genitalia, while those with milder or "nonclassic" forms will have normal genitalia at birth but may develop symptoms of hyperandrogenism in childhood or adulthood.

Other Forms of Virilizing Congenital Adrenal Hyperplasia β. CAH due to 3β-hydroxysteroid dehydrogenase deficiency and P450 oxidoreductase deficiency cause virilization in affected females, but also undervirilization in affected males, and therefore are causes of both 46,XX and 46,XY DSD. These conditions are discussed more in the section entitled "*46,XY Disorders in Androgen Synthesis or Action*."

increase in sex hormone-binding globulin (which binds testosterone and DHT) reduces the percentage of free androgen. Additionally, aromatase converts testosterone and androstenedione into estradiol and estrone, respectively. However, if excess maternal androgens are produced in high enough concentrations, placental aromatase activity may be overwhelmed, leading to masculinization of a 46,XX fetus. Fetal virilization has been reported with maternal luteoma of pregnancy, adrenal adenoma, hyperreactio luteinalis, metastatic carcinoma (Krukenberg tumor), CAH, and adrenal corticocarcinoma.[85,86] Maternal familial glucocorticoid resistance (characterized by manifestations of androgen and mineralocorticoid excess, with increased cortisol secretion without clinical signs of hypercortisolism) has also been associated with fetal virilization.[87] However, the overall occurrence of fetal virilization is rare, even in cases of significant maternal virilization. For example, among androgen-secreting luteomas of pregnancy, less than half of affected mothers develop symptomatic hyperandrogenism, and only 50% of female infants born to symptomatic mothers experience virilization.[86] Variability in fetal virilization may relate to proportion and type of androgens secreted, as some steroids are not substrates for aromatase and therefore cannot be converted to estrogens by placental aromatase. Gestational hyperandrogenism due to PCOS has not been shown to cause virilization in female infants, likely due to the protective mechanisms described above.[88]

Apart from endogenous maternal androgens, fetal virilization has been reported following maternal treatment with progestational agents (given to prolong a pregnancy threatened by spontaneous abortion), testosterone, and danazol.[89,90] Effects depend on the medication, dose, and duration. Iatrogenic fetal virilization has become very rare, because hormonal treatment is no longer advocated during pregnancy.

Aromatase Deficiency. The aromatase enzyme, a member of the cytochrome p450 superfamily, is encoded by the *CYP19* gene (located at 15q21) and catalyzes the synthesis of estrogens from androgens. Aromatase deficiency is an autosomal recessive condition due to a genetic defect in the fetal component of the placenta. During pregnancy, placental aromatase protects the fetus from maternally-derived androgens and protects the fetus and mother from high concentrations of androgens synthesized normally by the fetal adrenal. Therefore, deficiency in aromatase (OMIM 613546) results in virilization of a 46,XX fetus, as well as maternal virilization during pregnancy that resolves following delivery. As aromatase deficiency is also a feature of p450 oxidoreductase deficiency (OMIM 613571), a rare form of virilizing CAH (discussed in the section entitled "*46,XY Disorders of Androgen Synthesis or Action*"), it is critical to rule out cortisol deficiency in the fetus if the diagnosis is suspected. Beyond the newborn period, features of aromatase deficiency include pubertal failure, mild virilization, multicystic ovaries (due to hyperstimulation by follicle-stimulating hormone [FSH] and luteinizing hormone [LH] resulting from inability of the ovary to aromatase testosterone and androstenedione to estrogens), and delayed bone age (supporting the notion that estrogens drive fusion of epiphyses during puberty).[91] Biochemical findings include elevated androgens, low estrone and estradiol levels, and elevated gonadotropins (due to decrease in negative feedback from reduced estrogens).[92] Aromatase gene mutations can also produce "nonclassic" phenotypes: low residual aromatase activity may be sufficient for breast and uterine development to occur at puberty, despite significant androgenization *in utero.*[93]

Other Causes of 46,XX Differences of Sex Development

Disorders of Müllerian Development. In the absence of AMH, the Müllerian ducts develop into the fallopian tubes, uterus, and upper part of the vagina in 46,XX individuals. Although abnormal expression of AMH in a 46,XX individual may theoretically result in Müllerian duct anomalies, this condition has not been reported.[94] Mayer–Rokitansky–Küster–Hauser (MRKH) syndrome is a heterogeneous disorder referring to the congenital aplasia or hypoplasia of Müllerian duct derivatives, occurring in one out of 5000 newborn girls.[95] There are several subtypes of MRKH, including those in which the upper vagina, cervix, and uterus are solely affected, and other subtypes in which additional associated malformations occur, including renal, skeletal (including cervicothoracic somite dysplasia or MURCs association, OMIM 601076), cardiac, and hearing anomalies. Several candidate genes have been implicated in MRKH, including mutations in genes encoding transcription factors such as HNF1B (OMIM 137920, associated with renal malformations and maturity onset diabetes of the young type 5) and TBX-6.[96] A number of genes in the *WNT* family have also been associated with MRKH in human and animal models, most notably mutations in *WNT4,* which have occurred in individuals with MRKH and hyperandrogenism.[96] Müllerian anomalies have also been reported in other malformative syndromes (see Table 101.2). Müllerian and renal agenesis have been reported in velocardiofacial syndrome resulting from a deletion of chromosome 22q11.2 (OMIM 192430). Malformations of the vagina, uterus, and bladder occur in females with hand-foot-genital syndrome resulting from *HOXA13*

Figure 101.10 **Synthesis of dihydrotestosterone (DHT) via the classic and alternative (backdoor) pathways. A,** Synthesis of DHT from testosterone (classic) and androsterone (alternative). (From Wilson JD, Shaw G, Leihy ML, et al. The marsupial model for male phenotypic development. *Trends Endocrinol Metab*. 2002;13:78–83, with permission from Elsevier.) **B,** The classic pathway of steroidogenesis leading to DHT *(left)* and the alternative pathway *(right)*. The factors in the classic pathway are CYP11A1 (cholesterol side-chain cleavage enzyme, P450scc), StAR (steroidogenic acute regulatory protein), CYP17A1 (17α-hydroxylase/17,20-lyase, P450c17), HSD3B2 (3β-hydroxysteroid dehydrogenase, type 2), and HSD17B3 (17β-HSD3 [17β-hydroxysteroid dehydrogenase, type 3] and 5α-reductase, type 2 [5α-reductase 2, encoded by SRD5A2]). The alternative pathway is characterized by the presence of additional enzymes: 5α-reductase, type 1 (5α-reductase1, encoded by SRD5A1), AKR1C23 (3α-reductase, type 3) and possibly AKR1C4 (3α-reductase, type 1) and RoDH (3-hydroxyepimerase, encoded by HSD17B6). Most steroids are identified by their trivial names: 17-hydroxy-dihydroprogesterone (17OH-DHP) is 5α-pregnane-17α-ol-3,20 dione; 17-hydroxy-allo-pregnanolone (17OH-allo) is 5α-pregnan-3α,17α-diol-20-one; 5α-dihydroprogesterone (5α-DHP) is 5α-pregnane-3,20-dione, and allo-pregnanolone is 3α-hydroxy-dihydroprogesterone (3α-OH-DHP) or 5α-pregnane-3α-ol-20-one. (Reprinted from Flück CE, Meyer-Böni M, Pandey AV, et al. Why boys will be boys: Two pathways of fetal testicular androgen biosynthesis are needed for male sexual differentiation. *Am J Hum Genet*. 2011;89:201–218, with permission from Elsevier.)

mutations (OMIM 140000). Vaginal atresia has also been described in McKusick–Kaufman syndrome (OMIM 236700), probably caused by mutations in the *MKKS* gene. Another rare malformation syndrome closely related to MRKH is Herlyn–Werner–Wunderlich syndrome, characterized by uterus didelphys, blind hemivagina ,and ipsilateral renal agenesis.[97] Müllerian anomalies also occur in females with anorectal malformations and are commonly seen in those with cloacal exstrophy.[98]

Syndromic Disorders. Syndromic disorders leading to 46,XX DSD are discussed in the section entitled "*Syndromic DSD*."

KEY POINTS

- 46,XX differences in sex development (DSD) occur due to variations in gonadal development, fetal exposure to androgen excess, or abnormalities in Müllerian development, or in association with genetic syndromes. Excessive levels of androgens result in virilization of the external genitalia in a 46,XX individual. Congenital adrenal hyperplasia due to 21-hydroxylase deficiency is the most common cause of 46,XX DSD, and should be suspected in any infant with ambiguous or male-appearing genitalia and nonpalpable gonads.

46,XY Differences of Sex Development

Disruption in hormone signaling during the critical period of fetal development may result in 46,XY DSD. Insufficient androgen exposure (either due to impaired androgen synthesis or action) leads to undervirilized external genitalia and Wolffian duct regression; uterus may be present or absent depending on whether AMH production is impacted as well (see Fig. 101.8).

As these conditions are present early in fetal development, the androgen-dependent fusion of the urethral and labioscrotal folds (discussed earlier in the section entitled "*Male Sex Differentiation*") and elongation of the phallus is disrupted, leading to genital ambiguity (e.g., hypospadias and micropenis) or, in extreme cases, near-female–appearing external genitalia. The Quigley scale has been used to describe the appearance of external genitalia in 46,XY DSD (Fig. 101.11).

Isolated defects in AMH production or sensitivity are characterized by the existence of uterus and fallopian tubes in an otherwise normally virilized patient. 46,XY DSD may also result from nonhormonal causes, including intrauterine growth restriction and various genetic syndromes.

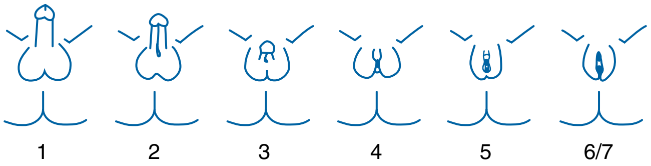

Figure 101.11 Schematic representation of Quigley scale, now widely used for classification of defective genital masculinization in 46,XY difference of sex development. Grades are numbered 1–7 in order of increasing severity (more defective masculinization). Grade 1: normal masculinization in utero; grade 2: male phenotype with mild defect in masculinization (e.g., isolated hypospadias); grade 3: male phenotype with severe defect in masculinization—small penis, perineoscrotal hypospadias, bifid scrotum, and/or cryptorchidism; grade 4: severe genital ambiguity—clitoral-like phallus, labioscrotal folds, single perineal orifice; grade 5: female phenotype with posterior labial fusion and clitoromegaly; grade 6/7: female phenotype (grade 6 if pubic hair present in adulthood, grade 7 if no pubic hair in adulthood). (Adapted from Quigley CA, Bellis ADE, Marschke KB, et al. Androgen receptor defects: Historical, clinical, and molecular perspectives. *Endocr Rev.* 1995;16:271–321.)

46,XY Differences in Gonadal Development

Pure Gonadal Dysgenesis. Pure, sometimes called complete, gonadal dysgenesis results in streak gonads that do not secrete sex steroids or AMH. Consequently, these patients have female internal and external genitalia. In 46,XY individuals, the condition is also known as Swyer syndrome or as complete sex reversal (a term that is no longer used). Absence of mammary development and primary amenorrhea are the most frequent presenting feature in a child reared unequivocally as a female. Adults with 46,XY gonadal dysgenesis are taller than those with 46,XX gonadal dysgenesis, which suggests the existence of a Y-specific growth gene that promotes growth independently of gonadal steroids.[99] Serum AMH is undetectable,

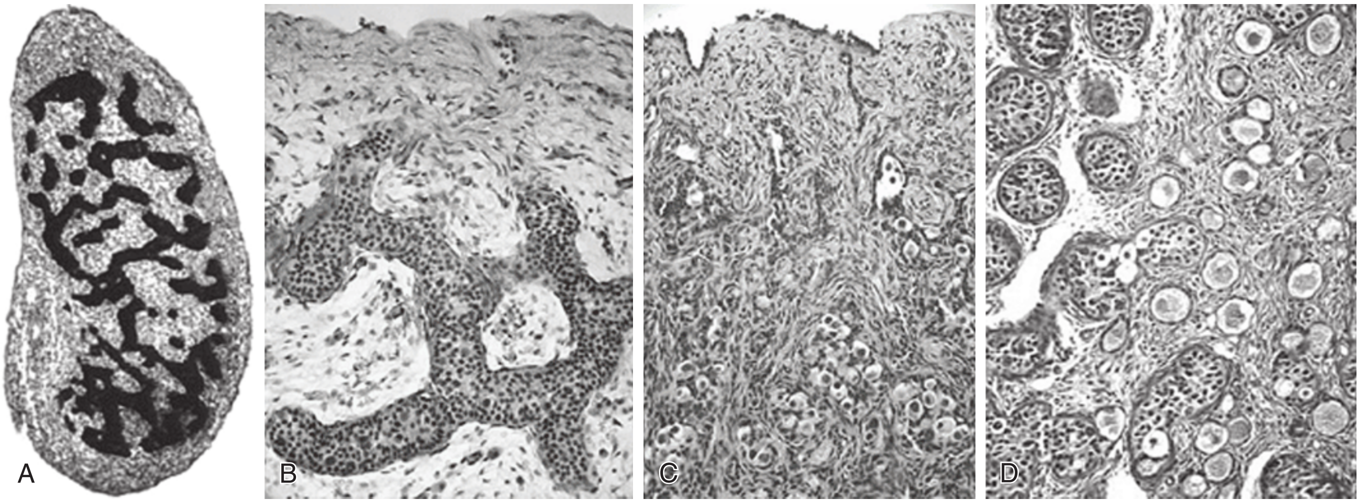

Figure 101.12 **A,** Normal testis of an 11-week-old fetus: anastomosing seminiferous cords, positively stained for anti-Müllerian hormone (AMH), form a typical network. **B,** Dysgenetic testis with abnormal seminiferous cords forming an anastomosing network. **C,** Streak gonad with abnormal germ cells. **D,** Ovotestis, showing seminiferous cords and follicles with oocytes. (Modified with permission from Chemes H, Muzulin PM, Venara MC, et al. Early manifestations of testicular dysgenesis in children: Pathological phenotypes, karyotype correlations and precursor stages of tumour development. *APMIS*. 2003;111:12–24. Copyright APMIS 2003.)

androgens (of adrenal origin) are low and do not respond to human chorionic gonadotropin (hCG) stimulation, and gonadotropin levels are elevated.[100] 46,XY patients are at increased risk for the development of gonadal tumors, gonadoblastoma, and dysgerminoma.[101]

Partial Gonadal Dysgenesis. The phenotypic differences resulting from partial gonadal dysgenesis (previously called dysgenetic male pseudohermaphroditism), which are observed in 46,XY DSD patients, depend on the extent of testicular differentiation. A mixture of Wolffian and Müllerian duct derivatives can be observed. A continuum of phenotypes ranging from almost-female genitalia with clitoromegaly to male genitalia with mild hypospadias and cryptorchidism has been described. In the most severe cases, gonadal tissue may contain areas of poorly differentiated seminiferous tubules in combination with areas of ovary-like stroma. These "streak-testes" should be distinguished from ovotestes, in which ovarian follicles are present.[102] All dysgenetic gonads in Y-chromosome-bearing patients have an increased risk for gonadal tumors.[29,101] Spontaneous breast development may provide the first evidence of an estrogen-secreting gonadal tumor. In milder forms, testes have distinct seminiferous tubules; however, the gonads are small, the albuginea is thin and loosely organized, and the seminiferous tubules are separated by wide intertubular spaces, frequently forming a network that resembles the first stages of sex cord formation in the developing testis and contains scarce germ cells (Fig. 101.12).[102] Ring tubules, calcified psamomma bodies, or a persistent coelomic epithelium can also be observed. A frequent surgical finding is the dissociation between testis and epididymis, joined only by a thin connective membrane. Serum testosterone, AMH, and inhibin B are intermediate between the male and female ranges, and gonadotropins are elevated, in correlation with the degree of dysgenesis.[100,103]

Mild Gonadal Dysgenesis. In the mildest forms, testes are almost normal, except for a reduced number of germ cells. Patients have normal male genitalia and hormonal levels within the expected range for sex and age. In some cases, gonadal dysgenesis is suspected by testicular-epididymal dissociation observed during surgery for cryptorchidism and is confirmed by histologic examination. In other cases, the first manifestation is observed in adults who present with infertility or testicular tumor.[104]

Asymmetric (Mixed) Gonadal Dysgenesis. As suggested by Jost's experiments,[1] the action of fetal testicular hormones is mainly local. This can be observed clearly in asymmetric gonadal differentiation, also called mixed gonadal dysgenesis, characterized by a dysgenetic testis on one side and a streak contralaterally. Patients usually, but not exclusively, present with male ducts and a palpable gonad in a hemiscrotum or inguinal canal on one side and a hemiuterus and an empty labioscrotal fold on the other side. The size of the phallus and the position of the urethral meatus are variable. The most commonly found karyotype in peripheral blood is 45,X/46,XY, but the karyotype may range from normal 46,XY to various mosaicisms. When studied in gonadal tissue, a 46,XY karyotype is more prevalent in the testis, and abnormal karyotypes are found in the streak.[102]

Testicular Regression Syndrome. Testicular regression syndrome (also known as congenital anorchia or vanishing testes syndrome) is a condition in which testes are thought to have been present early in fetal development but subsequently atrophied. The underlying etiology is unclear; bilateral testicular torsion has been theorized as a possible cause, though there may also be a genetic basis, including pathogenic variants of *DHX37*.[105] External genitalia appear typically male, though micropenis may be present due to interruption in androgen-induced phallic growth later in gestation. Uterus is typically absent, as AMH secretion early in fetal development is normal.

46,XY Ovotesticular Differences of Sex Development. Ovotesticular DSD has been described earlier in the section on 46,XX DSD; as noted, a minority of individuals with OT-DSD have a 46,XY karyotype.

46,XY Disorders in Androgen Synthesis or Action. Differences in androgen synthesis or action in a 46,XY individual cause undervirilized (ambiguous or female) external genitalia. As AMH production is normal, regression of Müllerian structures occurs normally, and these individuals have no uterus (see Fig. 101.8). Internal male genitalia may be absent, as testosterone is required for development of Wolffian ducts. Testes are present but may be intraabdominal or incompletely descended.

DSDs in this category include Leydig cell aplasia or hypoplasia, defects in cholesterol synthesis (Smith–Lemli–Opitz syndrome [SLOS]), enzymatic defects in testosterone biosynthesis (including rare forms of CAH impacting both adrenal and testicular steroidogenesis, as well as isolated defects in testicular steroidogenesis such as isolated 17,20-lyase deficiency and 17β-hydroxysteroid dehydrogenase III deficiency), defects in testosterone metabolism (5α-reductase type 2 deficiency), and defects in androgen action (including complete and partial androgen insensitivity syndrome).

Leydig Cell Aplasia or Hypoplasia. Leydig cell aplasia (OMIM 238320) is a rare autosomal recessive form of 46,XY DSD resulting from inactivating mutations of the LHCGR (located on chromosome 2p16.3),which is essential to Leydig cell differentiation and function before and after birth. In 46,XY individuals, impairment of prenatal and postnatal testosterone secretion results in a phenotypic spectrum ranging from predominantly female external genitalia without pubertal virilization in severe forms to micropenis and infertility. Owing to normal secretion of AMH by Sertoli cells, Müllerian derivatives are absent. Basal and hCG-stimulated testosterone levels are low, plasma LH is elevated, and FSH is normal. Testes are inguinal or intraabdominal and contain normal Sertoli cells but few or no mature Leydig cells.[106] In genetic females, the phenotype is usually limited to oligomenorrhea and infertility due to anovulation.

Smith–Lemli–Opitz Syndrome (Cholesterol Synthesis Defect). SLOS (OMIM 270400) is an autosomal recessive disorder caused by a defect in dehydrocholesterol reductase blocks the last step of cholesterol synthesis. SLOS has a wide phenotypic spectrum; however, features may include microcephaly, characteristic facial findings (e.g., low-set ears, short and broad nose, small chin), cleft palate, syndactyly of the second and third toes, cardiac and renal defects, growth retardation, developmental delays, and aggressive or self-injurious behavior. Intrauterine growth retardation can be noted prenatally. Hypospadias or bilateral cryptorchidism occurs in 50% of 46,XY patients, and sexual ambiguity with a rudimentary uterus is observed in severe cases. 46,XX patients usually have normal genitalia. The diagnostic biochemical finding is an elevated 7-dehydrocholesterol, the immediate precursor to cholesterol. SLOS results from mutations in the *DHCR7* gene (located on chromosome 11q13.4). During fetal development, cholesterol is required for steroidogenesis and for processing sonic hedgehog, which plays a major role in pattern formation of the nervous system, face, and limbs.[107] Although there have been several case reports of adrenal insufficiency in neonates with SLOS, abnormal adrenal function testing is not commonly seen in individuals with mild to moderate SLOS.[108]

Enzymatic Defects in Testosterone Biosynthesis. Five enzymatic activities are necessary for the synthesis of testosterone from cholesterol (see Fig. 101.7). Three are common to both the cortisol and testosterone biosynthetic pathways: cholesterol side-chain cleavage (P450scc), 3β-hydroxysteroid dehydrogenase (3β-HSD), and 17α-hydroxylase (P450c17). A deficiency in any of these activities results in both CAH and DSD in 46,XY patients. Two—17,20-lyase (activity contained in P450c17) and 17β-hydroxysteroid dehydrogenase (17β-HSD)—are required only for biosynthesis of sex steroids. P450 oxidoreductase (POR) supplies electrons to the steroidogenic enzymes P450c17, 21-hydroxylase, and aromatase; therefore, deficiency in POR results in CAH as well. The diagnosis of enzymatic defects in testosterone biosynthesis is typically based on biochemical markers and clinical features (see Table 101.4).

Steroidogenic defects leading to CAH (steroidogenic acute regulatory [StAR], p450scc, 3β-HSD, and combined 17α-hydroxylase/17,20-lyase deficiencies) are discussed in detail in Chapter 94 and are reviewed briefly here for completeness.

Lipoid Congenital Adrenal Hyperplasia and Cholesterol Side-Chain Cleavage Enzyme Deficiency. Lipoid CAH (LCAH, OMIM 201710) is a rare and severe form of CAH caused by defects in the StAR protein, which is involved in the very first step of steroidogenesis (see Fig. 101.7). The StAR protein accelerates the transport of cholesterol transport from outer to the inner mitochondrial membrane, following which the cholesterol side chain cleavage enzyme (cholesterol desmolase, CYP11A1, P450scc) removes the side chain of cholesterol to form pregnenolone. Deficiency in StAR protein impairs production of all adrenal and gonadal steroids directly by impacting the rate-limiting step of steroidogenesis, but also indirectly, as the accumulation of unutilized cholesterol esters induces apoptosis of steroidogenic cells. Steroidogenesis in the placenta is not dependent on StAR protein, and therefore adequate progesterone and estrogen is still produced to sustain a pregnancy in a fetus with LCAH. Mutations in cholesterol side chain cleavage enzyme (P450scc deficiency, OMIM 613743) are less common than StAR mutations but produce a similar phenotype to LCAH (except for the accumulation of intracellular cholesterol, which does not occur). In an affected 46,XY fetus, hCG-stimulated testosterone production does not occur, which prevents virilization of the external genitalia. Affected 46,XY newborns with the classic (most severe) form of LCAH or deficiency in cholesterol side chain cleavage enzyme may have phenotypically female external genitalia. 46,XX patients develop normally until puberty but subsequently develop polycystic ovaries without hyperandrogenism. Infants with classic forms may present with glucocorticoid and mineralocorticoid deficiencies leading to adrenal crisis and salt wasting. All steroid hormones in blood or urine are barely measurable at birth and do not respond to trophic hormone stimulation. Levels of plasma ACTH, plasma renin activity, and gonadotropins (at the time of hypothalamic-pituitary-gonadal [HPG] axis activation) are high. Milder, nonclassic forms with late onset, limited to adrenal insufficiency, have also been described.[109]

3β-Hydroxysteroid Dehydrogenase Type II Deficiency. 3β-hydroxysteroid dehydrogenase type II deficiency (3β-HSD2D) is a rare form of CAH that causes both 46,XX and 46,XY DSD. The 3β-HSD enzyme is responsible for the conversion of 3β-5 steroids to the 3-keto-4 configuration during the synthesis of glucocorticoids, mineralocorticoids, and sex steroids (see Fig. 101.7). 3β-HSD exits in two isoforms; however, only deficiencies in the type 2 isoform (3β-HSD2) expressed in adrenals and gonads leads to CAH. 3β-HSD2 expression is detectable in human testicular interstitial cells from 8 weeks' gestation; however, expression in fetal ovaries is not observed until 28 weeks; gestation. XY individuals are undervirilized with varying degrees of hypospadias and micropenis, and testes can usually be palpated in the groin. Although adrenal sex steroid production is impacted by the deficiency in 3β-HSD type 2 enzyme, conversion of dehydroepiandrosterone (DHEA) to more potent androgens by the unaffected 3β-HSD type 1 isoform (expressed in the placenta and peripheral tissues) leads to mild virilization of 46,XX infants. The affected female fetus may also be protected from severe masculinization due to physiologic variations in fetal cortisol synthesis and 3β-HSD2 expression, which peak early on (by 8–9 weeks' gestation), decline in midgestation, and rise again only in the third trimester.[110] Individuals with classic 3β-HSD2 have adrenal insufficiency with or without salt wasting. An elevated basal or ACTH-stimulated ratio of $\Delta 5$ versus $\Delta 4$ steroids or 17-hydroxypregnonolone >6600 ng/dL (200 nmol/L) may suggest the diagnosis (see Table 101.4).

P450 Oxidoreductase Deficiency. POR is a flavoprotein located in the endoplasmic reticulum of steroidogenic cells that transports electrons from nicotinamide adenine dinucleotide phosphate (NADPH) to all microsomal (type II) cytochrome P450 enzymes.

Three steroidogenic enzymes are affected by POR deficiency: 21-hydroxylase, P450c17 (preferentially 17,20-lyase activity with 17α-hydroxylase activity less affected), and aromatase (see Fig. 101.7). Deficiencies in POR may lead to DSD in both XX and XY individuals. In 46,XY POR deficiency, impaired 17,20-lyase activity decreases the synthesis of testosterone by the fetal testis in the second trimester of pregnancy. In 46,XX individuals, placental aromatase deficiency results in overproduction of fetoplacental androgens (see the section entitled "Aromatase Deficiency"). In addition, as a result of 21-hydroxylase deficiency and preferential inhibition of 17,20-lyase activity, there is overproduction of 17-hydroxyprogesterone and 17-hydroxypregnenolone, which subsequently leads to virilization via the "backdoor" pathway of DHT synthesis (see the section entitled "*Virilizing Congenital Adrenal Hyperplasias*" and Fig. 101.10). Due to decreased activity of placental aromatase, transient maternal virilization may also occur during pregnancy with an affected fetus. Affected individuals can experience glucocorticoid deficiency or hypertension (likely due to elevated levels of deoxycorticosterone resulting from 17α-hydroxylase deficiency). Patients with POR deficiency may also present with bone malformations (craniosynostosis, fusion of long bones, midface hypoplasia, choanal stenosis) that are indistinguishable from Antley–Bixler syndrome (ABS, OMIM 201750), possibly due to disruption of enzymes involved in cholesterol and/or retinoic acid metabolism.[111] More than 50 mutations in the *POR* gene (located at 7q11.23) have been identified, with high variability of clinical presentation, though homozygous null mutations tend to be lethal.[111] Milder forms of POR may not be associated with ABS, or even necessarily with genital ambiguity. Biochemical findings include elevated pregnenolone, progesterone, and 17-hydroxyprogesterone and decreased cortisol.

17α-Hydroxylase/17,20 Lyase Deficiency. A single microsomal enzyme, cytochrome P450c17 (encoded by *CYP17A1*, located at 10q24.3) catalyzes two consecutive oxidation reactions, the 17α-hydroxylase and 17,20-lyase reactions required for the adrenal glands and gonads to synthesize glucocorticoids and sex steroids (see Fig. 101.7). The 17α-hydroxylase reaction converts pregnenolone to 17-hydroxypregnenolone and progesterone to 17-hydroxyprogesterone, respectively, with the former being rate-limiting step in androgen biosynthesis. The 17,20-lyase reaction converts 17-hydroxypregnenolone to DHEA and catalyzes the equivalent conversion of 17-hydroxyprogesterone to androstenedione, although this latter reaction occurs much more slowly. Like all microsomal P450 enzymes, P450c17 receives electrons from NADPH via POR. Cytochrome b5, acting as an allosteric factor, promotes the interaction of the two molecules, further increasing 17,20-lyase activity. Deficiency in P450c17 (causing combined 17α-hydroxylase/17,20-lyase deficiency) is a rare cause of CAH, though frequency is higher in specific locales (for example, in Brazil, where it is the second most common cause of CAH after 21-OHD). Combined 17α-hydroxylase/17,20-lyase deficiency is often characterized in both sexes by hypertension and hypokalemia, which result from massive overproduction of the 17-deoxysteroids deoxycorticosterone and corticosterone; however, some patients may be normotensive.[112] Because of high production of corticosterone, which is a weak glucocorticoid, adrenal crisis is rarely observed. Lack of production of both gonadal and adrenal sex steroids results in severe undervirilization of 46,XY patients. Indeed, most XY patients have been raised as females because of a completely female external phenotype at birth, and they keep a female social sex at puberty. 46,XX patients have a normal phenotype at birth but fail to undergo puberty, and they may develop ovarian cysts because of excess gonadotropin stimulation.[113] Biochemical findings in combined 17α-hydroxylase/17,20-lyase deficiency include elevation in steroids proximal to the block (see Table 101.4), low levels of cortisol, androgen and estrogen precursors, elevated deoxycorticosterone and corticosterone, suppressed renin and aldosterone, and elevated FSH and LH concentrations.

Isolated 17,20 Lyase Deficiency. Individuals with 46,XY isolated 17,20-lyase deficiency (ILD) experience variable undervirilization due to exclusive loss of sex steroid synthesis. Due to retention of 17α-hydroxylase activity, other consequences of adrenal CYP17A1 deficiency (discussed earlier) are not typically seen. True isolated 17,20-lyase deficiency is extremely rare. A few cases of confirmed ILD involved mutations in the redox-partner binding surface of the CYP17A1 enzyme.[114] However, others with apparent "ILD" have been later found to have mutations in other genes including those encoding cytochrome b5 (CYB5A) and POR, and AKR1C2/AKR1C4 (3α-hydroxysteroid dehydrogenase enzymes involved in the "backdoor" pathway for DHT production, see Fig. 101.10). [115]

17β-Hydroxysteroid Dehydrogenase III Deficiency. The 17β-hydroxysteroid dehydrogenase III (17β-HSD) enzyme catalyzes the last step in testosterone biosynthesis (i.e., the reduction of androstenedione to testosterone, see Fig. 101.7). 17β-HSD type 3 deficiency (OMIM 264300) involves the testicular isoform of 17β-HSD, resulting in a DSD limited to 46,XY individuals. The condition may often be mistaken for androgen insensitivity at birth and 5α-reductase deficiency at puberty. Patients typically have intraabdominal or inguinal testes, predominantly female external genitalia, well-developed Wolffian structures, a blind vagina, and no uterus or tubes. Development of internal male structures has been attributed to the activity of 17β-HSD isozymes other than 17β-HSD3 converting testis-derived androstenedione to testosterone in the proximity of the Wolffian ducts. Undervirilization of external genitalia is due to insufficient testosterone at the level of the external genital primordia to act as a substrate for 5α-reductase conversion to DHT. Most patients are raised female and seek medical attention at puberty because of amenorrhea, poor breast development, and severe virilization sometimes accompanied by gynecomastia. At puberty, affected 46,XY individuals may develop male body habitus with abundant body and facial hair, enlargement of the penis and testes to normal adult size, and pigmentation and rugation of the labioscrotal folds. Approximately half of those not gonadectomized prepubertally switch to a male gender role, and individuals with the same mutation even within the same family may choose differently.[116] Biological findings include massive elevation in androstenedione compared to testosterone, which may be elicited with an hCG stimulation test in prepubertal children. A testosterone/androstenedione ratio less than 0.8 is considered diagnostic.[116] In newborns and pubertal patients, LH is elevated, and FSH is normal. Plasma levels of ACTH, glucocorticoid, and mineralocorticoid hormones are normal, which is expected because 17β-HSD is not involved in adrenal function. 17β-HSD occurs due to mutations in *HSD17B3* gene, located at chromosome 9q22.32 and inherited as an autosomal recessive trait. 17β-HSD deficiency is a rare disease, though incidence is higher in some regions, including the Gaza Strip. Over 45 mutations in *HSD17B3* have been reported, with the most common mutations being c.277 + 4A>T and p. R80Q.[117]

5α-Reductase Type 2 Deficiency. Testosterone itself is not a potent androgen; its reduced metabolite DHT is the main virilizing agent during male reproductive development. DHT is formed mainly in target tissues through reduction of testosterone by the microsomal enzyme 5α-reductase type 2, coded by the *SRD5A2* gene (located at 2p23.1). It is expressed in androgen target tissues such as the external genitalia, the urogenital sinus, and the prostate, and also the Wolffian ducts after they have differentiated into vasa deferentia and their accessories. Thus, testosterone, not DHT, controls Wolffian early development. Another functional isoenzyme of 5α-reductase, with a

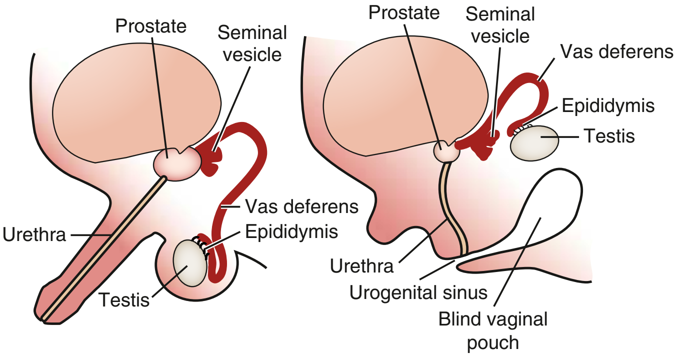

Figure 101.13 **Male genitalia.** Genitalia of a normal male *(left)* and that of a subject with 5α-reductase deficiency *(right),* illustrating the relative roles of testosterone and DHT in male sexual development. (Organs dependent on testosterone are shown in *red,* and those dependent on DHT are in the *lighter shaded* areas). (From Rey and Josso 119-9.Adapted from Imperato-McGinley J, Peterson RE. Male pseudohermaphroditism: The complexities of male phenotypic development. *Am J Med.* 1976;61:251–272.)

different pH optimum, 5α-reductase type 1, 50% homologous to type 2, is expressed after birth in the liver, transiently in neonatal skin, and permanently in skin from the time of puberty,[118] and its emergence probably accounts for pubertal virilization.

Steroid 5α-reductase isoform 2 deficiency (OMIM 264600) is a recessive autosomal disorder that is frequent in communities of Turkey, the Dominican Republic, and Papua New Guinea where consanguinity occurs, but relatively rare in other parts of the world.[119] It is clinically very similar to 17β-HSD3 deficiency, as both conditions are characterized by a poor virilization of the genitalia at birth, often limited to clitoromegaly; however, there is marked variability of the aspect of the genitalia even within the same family.[120] Microphallus associated with hypospadias and a urogenital sinus is not uncommon, and microphallus without genital ambiguity has even been reported.[119] At surgery, normal Wolffian duct derivatives are found that open in a blind vaginal pouch, and there is no uterus or tubes. The testes are usually extraabdominal, in the inguinal canal, the labia, or scrotum. More than two thirds of the patients are raised female, sometimes unequivocally until puberty. Then, if the testes have been left in place, the voice deepens, muscle mass and body hair increase, the phallus enlarges, a typical masculine habitus develops, and some patients transition their gender identity from female to male (Fig. 101.13). Gynecomastia is rare, and the prostate remains small. The sperm count is variable, from azoospermia to normal,[121] and fertility has been reported.[122] Infants with predominantly male phenotype are typically raised as males; however, some advocate for male gender assignment for all infants, given the occurrence of virilization later in life.

Biochemical findings include elevated testosterone/DHT ratio, when testosterone and DHT are expressed in the same units. Basal concentrations of testosterone and DHT are often insufficient to make the diagnosis prior to puberty, and hCG stimulation testing is usually required in prepubertal children. While the testosterone/DHT ratio in affected individuals most often exceeds 20,[120] lower ratios (>8.5) may be seen in the neonatal period.[123] Unlike in androgen insensitivity, where AMH is elevated, AMH serum values are not elevated in 5α-reductase type 2 deficiency, indicating that testosterone does not need to be converted to DHT to inhibit AMH production by Sertoli cells.[124]

More than 50 different mutations in *SRD5A2* have been reported, most commonly point mutations. Homozygous mutations are seen in over a third of patients, consistent with frequent finding of familial consanguinity. Other patients have compound heterozygote mutations.[119]

Androgen Insensitivity. Testosterone and DHT exert their action on androgen-dependent tissues by binding to the AR, which is a 110-kD member of the steroid receptor family. A long N-terminal domain, involved in transactivation, is coded by the first exon and harbors polyglutamine and polyglycine repeats. A conserved cysteine-rich DNA-binding domain (exons 2 and 3) is connected by a short hinge region to the ligand-binding domain (exons 4–8).[125] After binding to DHT or testosterone in the cytoplasm, the receptor is translocated to the nucleus, where it activates androgen-response elements in the promoter of androgen-responsive genes and initiates transcription. Nuclear localization is controlled by a nuclear localization signal spanning part of the DNA-binding domain and the hinge region, competing with an androgen-regulated nuclear export signal in the ligand-binding domain.[126] AR transactivation is enhanced by coregulators.[127,128] Eleven alpha-helices and four short beta-strands are involved in the formation of the ligand-binding pocket and the interaction surface for coactivators.[129]

The *AR* gene maps to Xq12, and its eight exons span approximately 186 kb. Over 1000 *AR* gene mutations have been recorded in the McGill University database (http://www.androgendb.mcgill.ca).[130] Mutations in the AR cause abnormalities in the formation of the steroid receptor–coregulator complex, its nuclear transport, its binding to DNA, or its transcriptional activation ability, causing complete or partial androgen insensitivity syndromes (PAIS). Inheritance is recessive X-linked and consequently causes DSD only in 46,XY individuals. The DSD phenotype in 46,XY individuals is variable, ranging from normal external female genitalia in complete androgen insensitivity syndrome (CAIS) to undervirilized male genitalia in PAIS. Additionally, more mild forms exist in 46,XY individuals associated with infertility and/or gynecomastia but with normal external male genitalia.

Complete Androgen Insensitivity Syndrome. CAIS is the most common cause of DSD in 46,XY completely feminized subjects, with an estimated prevalence of between 1/20,000 and 1/99,000.[131] Patients appear as normal females at birth. They may be diagnosed in infancy because of an inguinal hernia containing a palpable gonad that turns out to be a testis, or prenatally because of discordance between genotype and phenotype. Chorionic villus sampling at 10 to 12 weeks followed by sequencing of the AR in XY fetuses is useful in carrier mothers. Otherwise, patients come to medical attention at puberty because of primary amenorrhea. Feminine body contours and generous breast development are results of unopposed action of estrogens derived from androgen aromatization. Pubic and axillary hair are absent or sparse. The vagina is short and blind-ending, and the uterus is absent. Final height in CAIS is above normal mean female height, likely related to growth-controlling genes on the Y chromosome.[132]

Although Wolffian duct derivatives are not expected to develop in CAIS, Wolffian structures have been described in some cases and are thought to be related to residual activity of the AR that responds to the high local concentrations of androgen.[133] Müllerian remnants may also be found.[134] The testes are usually located in the inguinal canal or the labia majora. Testes were previously removed as early as possible after diagnosis due to concerns for risk of germ cell tumors, necessitating long-term estrogen supplementation. However, as the risk of malignant degeneration appears to be negligible before puberty, and relatively low in adults (estimated risk of 0.8%–2%), it is now recommended to delay gonadectomy to allow for spontaneous puberty through the aromatization of testosterone.[29,135] If gonadectomy is deferred, gonads may be monitored regularly by ultrasound or magnetic resonance imaging (MRI); however, these surveillance methods have not been systematically evaluated.[136] Vaginal dilation may be initiated after puberty or prior to initiating sexual activity, with the majority of patients achieving satisfactory response without requiring vaginoplasty.[137] Because of their apparently normal female phenotype and absence of exposure to male androgens, a female gender assignment is universally recommended.

Serum testosterone level is either within or above the normal range, and LH levels are high, but this pattern is evocative of hormone resistance and develops only after puberty. In the infant at 30 and 60 days of age, plasma testosterone values are below the normal range, and plasma LH values are low.[138] In contrast, the testosterone response to hCG is similar to or greater than that of normal infants. Plasma AMH levels may be normal or above the male reference range, relating to lack of inhibition of Sertoli cell function. Postpuberty, estradiol levels may be normal or slightly elevated for a male patient.[139] FSH levels are usually normal.

CAIS results from *AR* mutations that completely abolish the capacity of the receptor to mediate androgen action, for instance the creation of stop codons and frameshifts leading to premature termination of transcription resulting from insertions, deletions, or splice mutations. Most CAIS mutations occur in the ligand-binding domain, and nearly all mutations in exon 1 lead to CAIS.[130]

Partial Androgen Insensitivity Syndrome. The incidence of PAIS is difficult to determine, because some groups label as PAIS many 46,XY DSD cases of unknown etiology, even if *AR* mutations have not been found.[140] Clinically, PAIS is defined by some degree of virilization, which may range from predominantly female genitalia with slight degree of labial fusion to phenotypic males with hypospadias and micropenis. The aspect at birth is nonspecific, and diagnosis is difficult in the absence of family history. Hormone levels in individuals with PAIS may be similar to those with CAIS.[139] At puberty, scanty pubic and axillary hair and gynecomastia are suggestive of the diagnosis.

Whereas *AR* mutations are found in nearly all CAIS cases with usual sequencing methods, they can be detected in a large proportion of generation methods. Variants in exons 5 to 6 that encode the ligand-binding domain are more frequent in PAIS.[139] There is poor genotype/phenotype correlation, and the same mutation can result in widely different phenotypes even within the same kindred.[139]

Establishing a diagnosis of PAIS may be challenging, and other causes of 46,XY DSD must be considered. A short course of course of testosterone treatment (25 mg monthly for 3 months) may be useful to test androgen responsiveness; however, a positive response in infancy does not predict normal penile development at the time of puberty. Individuals with mild PAIS may present with male infertility and/or pubertal gynecomastia; however, external genitalia are normal. Elevated serum LH and testosterone levels may be found.[139] Most *AR* mutations leading to mild PAIS are found in the region encoding the N-terminal domain and involve single-base substitutions.[130]

Persistent Müllerian Duct Syndrome. Defective AMH production or sensitivity, which is rare, is characterized by the existence of uterus and fallopian tubes in an otherwise normally virilized patient. Regression of Müllerian ducts normally occurs between 8 and 10 weeks of fetal development, under the influence of AMH, a glycoprotein dimer member of the TGF-β family abundantly produced by fetal Sertoli cells. If active AMH is not produced, or if Müllerian ducts are insensitive to its action, Müllerian ducts develop into the uterus, fallopian tubes, and upper vagina notwithstanding normal virilization of external genitalia and urogenital sinus. Persistent Müllerian duct syndrome (PMDS) (OMIM 261550) is a rare, autosomal recessive condition that most commonly results from mutations of the *AMH* or AMH receptor type II genes, though idiopathic forms with no identified molecular cause have also been reported. The presence of Müllerian derivatives is often discovered incidentally; however, PMDS may also present as bilateral cryptorchidism (with the uterus fixed in the pelvis and both testes embedded in the broad ligament in an "ovarian" location), unilateral cryptorchidism, or with both testes in the same scrotal sac (a condition known as "transverse testicular ectopia").[142] Various congenital anomalies may occur with PMDS, including intestinal defects, renal anomalies, and low birth weight. In general, patients are infertile, although some cases of normal spermatogenesis have been reported.[142] Homozygous females are asymptomatic and fertile. AMH levels are low or undetectable in those with *AMH* mutations and normal in those with receptor mutations. Other hormone levels including gonadotropins and testosterone are normal.

Other Causes of 46,XY Differences of Sex Development. Although isolated hypospadias is quite common, evaluation for DSD should be considered in any infant with severe (penoscrotal) hypospadias, or in cases of milder hypospadias accompanied by micropenis or undescended testes. Rarely, 46,XY DSD has been associated with *in utero* exposure to endocrine disruptors, including phenytoin, phenobarbital, and other environmental exposures; however, a causative relationship has not clearly been established in humans.[143,144] Among individuals with 46,XY DSD of unclear etiology, nearly a third had prematurity and intrauterine growth restriction.[103] Although the mechanism for this association between low birth weight and hypospadias is unclear, placental insufficiency has been theorized as a possible cause.[145] 46,XY DSD may also be associated with genetic syndromes (see the section entitled "*Syndromic DSD*").

KEY POINTS

- Disruption in critical hormone signaling during fetal development may result in 46,XY difference in sex development (DSD). Insufficient androgen exposure leads to undervirilized external genitalia, while Müllerian derivatives may develop in the absence of anti-Müllerian hormone (AMH). Causes of 46,XY DSD include differences in gonadal development, disorders in androgen synthesis or action, disorders in AMH synthesis or action, and genetic syndromes.

Sex Chromosome Differences of Sex Development

Sex chromosome aneuploidies usually do not represent a differential diagnosis in patients with ambiguous genitalia; however, they are briefly described here because of their atypical sex chromosome constitution.

Turner Syndrome. TS is a chromosomal disorder that involving phenotypic females with a single intact X chromosome and complete or partial absence of the second sex chromosome, along with characteristic clinical manifestations. TS occurs in approximately 25 to 50 per 100,000 females. Forty to fifty percent of TS cases are caused my monosomy X (46,X); however, a variety of other chromosomal abnormalities may result in the condition, including mosaic forms (e.g., 45,X/46,XX, 45,X/47,XXX, 45,X/46,XX/4,XXX), mixed gonadal dysgenesis (45,X/46,XY), X chromosome deletions (e.g., deletion Xp22.3), ring X chromosomes (46,X,r(X)/46,XX), and isochromosomes made from two parts of the long i(X)q or two parts of the short chromosome segment i(Xp).[146] The syndrome spans a wide spectrum of clinical presentations.[147] The main characteristics are abnormal physical features, gonadal dysgenesis, and short stature. Follicles do not develop in the fetal gonad, which evolve to streaks.[148] Gonadotropin levels are found to be above the normal range[149] but may be normal between 6 and 9 years of age,[150] and AMH is undetectable[151] throughout childhood in girls with a 45,X karyotype. Children with TS may also have a short, thick, and webbed neck, hypertelorism, epicanthus and ptosis of the eyelids, low posterior hairline, congenital lymphedema, broad childlike chest, cubitus valgus and short fourth metacarpals, multiple pigmented nevi, intestinal telangiectasia, recurrent otitis media, and a tendency for keloid formation. TS patients have an increased incidence of celiac disease, cardiovascular defects (especially coarctation of the aorta and nonstenotic bicuspid aorta), kidney anomalies, chronic lymphocytic thyroiditis, diabetes mellitus, rheumatoid arthritis, and inflammatory bowel disease. Bone age is delayed, and bone mineral density may be affected. Compared to individuals with a 45,X karyotype, individuals with mosaicism (45,X/46,XX) tend to have a milder phenotype and may exhibit partial gonadal dysgenesis. These individuals may be diagnosed following spontaneous pubertal onset due to development of primary amenorrhea or premature ovarian failure. TS patients with a Y chromosome have an increased risk of gonadoblastoma, and gonadectomy is recommended in these individuals.

Klinefelter Syndrome. Klinefelter syndrome, the most common cause of male hypogonadism, with a prevalence of approximately 1.5 in 1000 males, was first described in 1942 as the association of eunuchoidism, gynecomastia, small testes, azoospermia, and elevated FSH excretion.[152] Several groups subsequently reported that a high proportion of patients with this syndrome were chromatin-positive, a finding explained in 1959 when the XXY constitution was reported.[153] Patients with the 47,XXY genotype have classic Klinefelter syndrome. Since the mid-1980s, the clinical spectrum of the syndrome has expanded to include patients with pure cell lines or mosaicisms with two or more X chromosomes and a Y chromosome.[154] However, some authors warn that patients with 48,XXYY, 48,XXXY, and 49,XXXXY polysomies present more complex physical, medical, and psychological phenotypes and should not be considered as having Klinefelter syndrome, even though they share features of hypergonadotropic hypogonadism.[155]

Gonadal dysgenesis primarily affects germ cells beginning in early fetal life[156] but does not impair Leydig and Sertoli cell function until midpuberty.[157] Therefore, internal and external genitalia are normally virilized in Klinefelter patients. Generally, at birth, no particular stigmata occur in Klinefelter syndrome. During childhood, no specific signs or symptoms are noted, except for bilateral cryptorchidism, learning disabilities, or behavior disorders, which are frequent.[158] Klinefelter boys are long-legged, most probably as the result of an overdose of *SHOX* gene expression.[46]

Pubertal development usually occurs spontaneously. In all cases, the predominant features are the small size of the testes (100%), which do not increase normally at puberty, and pubertal gynecomastia (60%). At puberty, as the gonadotropins increase, the seminiferous tubules do not enlarge but rather undergo fibrosis and hyalinization, which results in small, firm testes. Obliteration of the seminiferous tubules results in azoospermia. The marked reduction of tubular volume accounts for the apparent hyperplasia of the interstitial tissue. Leydig cells are present in clumps, and although their total mass is normal, they are functionally abnormal, resulting in a reduced testosterone production rate with compensatory LH hypersecretion. Because of the high LH levels, estradiol secretion is stimulated, with an increased estradiol/testosterone ratio, which is believed to account for the development of gynecomastia.[46,154]

47,XYY Males and 47,XXX Females. Although the prevalence of these conditions is approximately one in 1000 live births,[158] they are rarely diagnosed. Most cases are oligo- or asymptomatic. Gonadal development and function are normal in the vast majority of cases, except for a few XXX women who have been reported to develop premature ovarian failure.[159] Children are long-legged, with accelerated growth from infancy resulting in increased height at pubertal onset, and they may show behavior disturbances.[158]

Mosaic 45,X/46,XY Mixed Gonadal Dysgenesis. Mixed (or asymmetric) gonadal dysgenesis has been described in the section entitled "*46, XY Differences in Gonadal Development*."

Syndromic Differences of Sex Development

DSD in 46,XX and 46,XY may be isolated, with only gonadal or genital development affected, but may also be part of a syndrome affecting multiple organs. Syndromes involving a DSD symptom, as well as their genetic etiology, are presented in Table 101.2.

KEY POINTS

- Differences of sex development (DSD) are a spectrum of phenotypes encompassing variations of the development of the sex chromosomes, gonads, or urogenital tract. Pathophysiology of DSD depends on genetic and endocrine causes, which can be classified as 46,XX DSD, 46,XY DSD, and sex chromosome DSD.

EVALUATION AND MANAGEMENT OF DIFFERENCES OF SEX DEVELOPMENT

Management of DSD is complex, as the conditions may be associated with increased infertility, cancer, and gender dysphoria risks, as well as pervasive challenges to psychosocial adaptation for patients and families.[160-165] Correlation between treatment interventions (surgical, hormonal, psychosocial) and their clinical outcomes is poorly understood. This suggests that further research in DSD pathophysiology is needed to provide optimal evidence-based clinical management. Major challenges in DSD management include lack of standardization in descriptions of phenotype and medical/surgical interventions, resulting in variations in diagnostic and treatment practices across medical, surgical, and behavioral aspects of health.[164] Substantial unexplained variance in outcomes is revealed by studies examining the relationship between molecular diagnosis, gender development, and psychosocial trajectories.[166] These challenges complicate the principles of clinical management of DSDs, with disagreements among and between healthcare providers, advocacy groups, and patient communities regarding the definition of optimal care.[167] International efforts are underway to standardize practice and diagnosis.[30,168]

Tools in Differences of Sex Development Evaluation

Genetic Testing. From a diagnostic standpoint too, DSDs are challenging. For example, 46,XY disorders of androgen biosynthesis, which include SRDA2, 17β-HSD, 3β-HSD, StAR, CYP17A1, and POR deficiencies, are often difficult to distinguish clinically. However, an early genetic diagnosis is critical, as these conditions have drastically different natural histories requiring different management (recently reviewed in [24]). The various tools used for genetic evaluation, their clinical availability, and their turnaround time are described in Table 101.5.

Hormonal Testing. Biochemical assessments to evaluate gonadal and adrenal function are useful for diagnosis of DSD. To best evaluate gonadal function in an infant, timing of sex-steroid measurement should correspond to activation of the HPG axis. In boys, serum testosterone may rise for approximately 12 hours after birth, corresponding to a brief physiologic surge in LH after delivery.[169] The HPG axis is

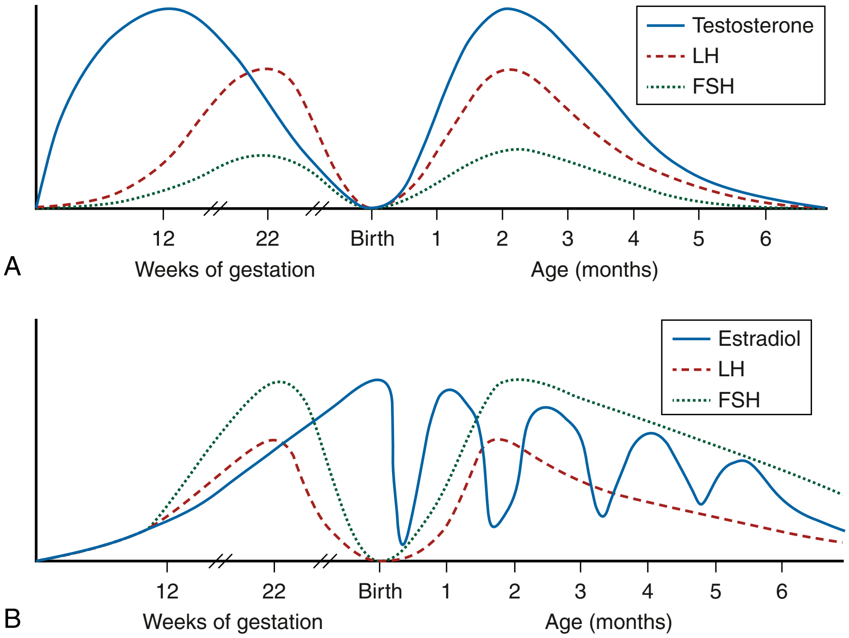

Figure 101.14 Patterns of fetal and postnatal gonadotropins and sex steroids. **A,** Males. **B,** Females. *LH*, Luteinizing hormone; *FSH*, follicle-stimulating hormone. (Adapted from Lanciotti L, Cofini M, Leonardi A, et al. Up-to-date review about minipuberty and overview on hypothalamic-pituitary-gonadal axis activation in fetal and neonatal life. *Front Endocrinol (Lausanne)*. 2018.)

subsequently suppressed but reactivated by around 1 week of life at the start of the "minipuberty" of infancy. Testosterone levels peak between 2 to 10 weeks of life but subsequently decline by 4 to 6 months at the end of the minipuberty. In girls, gonadotropin levels also begin to rise within the first week of life; however, FSH levels are higher and may remain elevated until 3 to 4 years of age. Estradiol levels often fluctuate during the minipuberty and typically decline by the second year of life[169] (Fig. 101.14).

Measurement of LH is useful to confirm activation of the HPG axis; if the LH level is low in the first 2 weeks of life, testing may be repeated at 1 to 3 months of life. AMH and inhibin B, both secreted by Sertoli cells, can be useful markers of testicular tissue even beyond the minipuberty period. Boys have significantly higher AMH values (>30 ng/dL) compared with girls, from infancy to puberty. Evaluation for ovarian tissue is more challenging due to the absence of a reliable marker, particularly in cases where testicular tissue may also be present (i.e., in OT-DSD). Proposed approaches to detect ovarian tissue have included measurement of inhibin A levels[170] and estradiol response to human menopausal gonadotropins[171]; limited evidence exists to support these methods. In older infants and prepubertal children with male-range

AMH, hCG stimulation testing may be utilized to evaluate testicular hormonal function. Protocols for hCG stimulation testing vary widely but often involve multiple doses of hCG given over 2 to 3 days, as well as laboratory measurements (typically testosterone, androstenedione, and DHT) at baseline and poststimulation.[172] The interpretation of hCG stimulation test results is also variable and may depend on testing protocol and other subject characteristics; however, stimulated ratios of testosterone to other androgen metabolites may be informative to evaluate for disorders of androgen biosynthesis or metabolism (e.g., ratio of testosterone to DHT of >10 may suggest 5α-reductase type 2 deficiency and ratio of testosterone to androstenedione <0.8 may suggest 17β-hydroxysteroid dehydrogenase type III deficiency). Given the increasing ability to provide genetic diagnoses for DSD, hCG stimulation may not always be required. Assessment of adrenal function is critical for both for diagnostic purposes and to rule out life-threatening complications of CAH. Serum electrolytes including sodium, potassium, and glucose should be measured in any infant in whom CAH may be possible. Aldosterone and plasma-renin activity may be useful to evaluate for salt-wasting CAH phenotype. 17-OHP is used to evaluate for 21-OHD (the most common cause of 46,XX DSD); basal levels will be markedly elevated in classic 21-OHD. Other adrenal metabolites should be measured when evaluating rarer forms of CAH (see Table 101.4); however, basal levels may not always be sufficient, and often the ACTH stimulation test is required to satisfy the diagnosis (see Chapter 94 for details). Plasma or serum steroid measurements should be performed by liquid chromatography–mass spectroscopy, or alternatively, immunoassays after extraction given the potential for crossreactivity.[172]

Imaging Studies and Other Procedures. Imaging modalities are utilized to detect internal genital structures (i.e., presence or absence of a uterus) and to localize gonads. Ultrasonography is the primary imaging modality in DSD evaluation and is particularly useful in the neonatal period, when the uterus and ovaries are prominent due to maternal hormonal stimulation. MRI can provide more detailed anatomic information and may be more sensitive than ultrasound in detection of intraabdominal gonads.[173] Voiding cystourethrography and genitography may be used to define the internal genital anatomy and to delineate the level of confluence of the vagina and urethra. Computed tomography is the preferred modality to evaluate for malignancies in DSD. Surgical procedures are also utilized in DSD evaluation. An examination under anesthesia combined with a diagnostic vaginoscopy is commonly used to evaluate the lower genital tract in pediatric and adolescent patients.[174] Diagnostic laparoscopy and gonadal biopsy are useful to evaluate gonadal status in complex DSD conditions.

Initial Evaluation of a Newborn with Atypical Genital Appearance

The first step in the DSD evaluation of a newborn is a thorough clinical examination to determine if gonads are palpable (in the labioscrotal folds or inguinal canal), as this will determine the choice and order of the investigation. Infants with atypical genital appearance and nonpalpable gonads must immediately be evaluated for virilizing CAH, due to the possibility of life-threatening complications related to glucocorticoid and/or mineralocorticoid deficiencies. As gonads palpable below the inguinal ligament typically contain testicular tissue, 46,XY DSD may be more likely in this situation. Absence of a uterus (which may be ascertained by ultrasonography) also suggests the presence of testicular tissue that produced AMH. Rapid identification of sex chromosomes via karyotype or other means (e.g., fluorescence *in situ* hybridization for *SRY*) help characterize the DSD (i.e., as 46,XX, 46,XY or sex chromosome DSD), which will provide a framework for the differential diagnosis and subsequent workup (Fig. 101.15). A detailed physical examination may reveal other findings suggestive of the underlying diagnosis. For example, pigmentation of the genitalia and nipples or elevated blood pressure may suggest a form of CAH (see Table 101.4). Other congenital anomalies may suggest an underlying genetic syndrome associated with DSD (see Table 101.2). Family history may be informative to elucidate a genetic mode of transmission; maternal gestational history should also be obtained including prenatal exposures or occurrence of maternal virilization (see the sections entitled "*Maternal-derived Androgens*" and "*Aromatase Deficiency*").

In infants with suspected 46,XX DSD, serum 17-OHP level and electrolytes should be measured to rule out CAH due to 21-OHD. Close monitoring is required, as salt wasting may present at a few days to several weeks of life. Findings of extremely high levels (to 10,000 ng/dL or 300 nmol/L) of 17-OHP are diagnostic of 21-OHD, whereas mildly elevated 17-OHP levels may suggest other forms of virilizing CAH; diagnosis may require measurement of other adrenal metabolites and ACTH stimulation testing (see the section entitled "*Virilizing Congenital Adrenal Hyperplasias*" and Table 101.4). In virilized 46,XX infants, an AMH level above the female reference range is suggestive of testicular tissue; therefore, 46,XX testicular or OT-DSD should be considered.

Evaluation of 46,XY DSD depends on measured testosterone and AMH levels. As discussed above, testosterone should be measured during the "minipuberty" of infancy and with concomitant gonadotropins to ensure activation of the HPG axis. Individuals with low testosterone and AMH are likely to have testicular dysgenesis, as both Leydig and Sertoli cell populations are affected. When testosterone is low but AMH is within or above normal, only Leydig function is affected (see Fig. 101.8). Adrenal function must be assessed to rule out rare forms of CAH that impact both adrenal and testicular steroidogenesis (e.g., LCAH, 3β-HSD, P450c17 deficiency, POR deficiency, see Table 101.4). If adrenal function is normal, disorders that impact testicular biosynthesis or secretion (e.g., Leydig cell hypoplasia, 17β-HSD) should be considered. When both testosterone and AMH are within or above the male range, primary hypogonadism can be ruled out, and androgen end-organ defects should be suspected. In patients with completely female genitalia, CAIS is most likely. Conversely, in patients with ambiguous genitalia, PAIS or 5α-reductase type 2 deficiency should be considered. A high testosterone/DHT ratio is predictive of 5α-reductase type 2 deficiency; however, elevated ratios can sometimes occur in androgen insensitivity syndrome because the expression of 5α-reductase type 2 gene (*SRD5A2*) is upregulated by androgens. Elevated AMH is suggestive of PAIS, in that AMH is normal in 5α-reductase type 2 deficiency, but overlapping can be seen.

Initial Gender Assignment

Gender uncertainty in a newborn is extremely stressful for the family. Speed in achieving a thorough assessment and reaching a decision is required. However, erroneous gender assignment and the need for reassignment could be more harmful for the patient's future than delaying the decision. Although in some cases rapid chromosomal, genetic, and biochemical analyses may lead to an immediate diagnosis and gender assignment, in other situations weeks are needed before a decision can be made. The clinician should tell the parents that recognition of the sex of the child is difficult on simple external examination and can be achieved only after complete investigation rather than saying that the child is neither a boy nor a girl. It is prudent to delay the mention of sex on the birth certificate until biological and molecular results are available to an expert team of specialists and the parents have had time to consider the various options. Factors that influence gender assignment include diagnosis, genital appearance, surgical options, need for lifelong hormone replacement therapy, potential for fertility, views of the family, and, sometimes, circumstances related to cultural practices.

KEY POINTS

- Initial evaluation of a newborn with atypical genital appearance depends on the location of the gonads; newborns with nonpalpable gonads should be evaluated for congenital adrenal hyperplasia. Identification of sex chromosomes directs subsequent differences of sex development evaluation, which may include genetic testing, hormonal testing, and imaging studies. Gender assignment in newborns should be delayed until expert evaluation has occurred. Open communication with the family is essential.

Management of Differences of Sex Development

Differences of Sex Development Healthcare Teams. A key feature of care recommended for children with a DSD is the presence of a multidisciplinary team. Composition may vary, but this team often includes specialists from endocrinology, genetics, surgery, gynecology, mental health, and ethics. Access to advocacy and/or patient support groups is also extremely important in the context of patient-centered care. A shared decision-making protocol should be in place, emphasizing open communication between the team and the family. Protocols to ensure transition from childhood to adult care should be in place.

Hormonal Management. Sex steroids may be used for induction of puberty and for long-term hormone replacement in DSD patients. Insufficient sex hormone exposure may impact development of secondary sex characteristics, physical growth, bone mineral density, and psychological functioning. Choice of sex hormone replacement is based on the underlying diagnosis, sex of rearing, and gender identity of the patient. Testosterone supplementation, typically with intramuscular depot injections, is used for penile enlargement in infancy and for induction of male puberty in individuals with gonadal dysgenesis and disorders of androgen synthesis (i.e., Leydig cell hypoplasia and testicular steroidogenic defects) who are being reared as males. In males with mild 5α-reductase deficiency, virilization is feasible with androgen therapy (high doses of testosterone or DHT creams) and typically occurs spontaneously at puberty; however, the outcome is most likely satisfactory provided that they show a sufficient degree of virilization at birth. The situation is less clear-cut in PAIS patients, in that the response to androgen treatment is less efficient. Patients with PAIS reared as males may require supraphysiologic doses of testosterone for optimal effect. Topical DHT cream has also been used to treat micropenis in PAIS patients with variable success.[175] Transdermal estradiol is typically used for induction of female puberty in patients being raised as females; various formulations exist for long-term supplementation. Progesterone should also be utilized in patients with a uterus to avoid deleterious effects of unopposed estrogen on the endometrium. Gonadotropin-releasing hormone agonist therapy may be used to suppress endogenous production of pubertal sex hormones. This approach may be useful to prevent exposure to sex hormones that are inconsistent with the gender of rearing or gender identity and may preclude the need for early gonadectomy to prevent pubertal virilization in those being raised as females.

Patients with DSD due to CAH may be treated with glucocorticoid and mineralocorticoid supplementation; management of these patients is discussed in Chapter 94.

Surgery. The traditional approach of surgical care has been to create an anatomy matching the sex of rearing, with the goal of influencing gender identity and allowing sexual intercourse congruent with a heterosexual sexuality in the gender assigned. Needless to say, this view has become more and more controversial. Advocacy groups have challenged the practice of early genital surgery, citing patient autonomy as well as lack of long-term favorable outcome studies, with, in particular, the risk that sexual sensation and function could be impaired because of surgery.

The consensus statement has provided guidelines for a more cautious approach to surgery. The statement proposes that the consequences of surgery be explained in detail, including risks of complications. It also requires that surgeries be performed in centers of excellence by surgeons experienced in DSD care. The statement also suggests that clitoral surgery should only be considered in the most masculinized cases (Prader 3 to 5), and that no vaginal intervention (vaginoplasty) be performed in infancy. The debates about surgery have continued to rage, with a growing movement considering that genital surgery in infancy is equivalent to a human rights violation. In contrast, calls for obtaining outcome data comparing the effects of surgical intervention versus alternative care (nonsurgical) have been made, albeit with limited success.

Risk of Tumor Development. DSD patients with gonads containing Y-chromosome material may be at risk for gonadal malignancy. The risk appears to be greatest in those with dysgenetic gonads and in those with intraabdominal as compared to inguinal or scrotal gonads. The highest risk is among individuals with testis-specific protein Y-encoded (*TSPY*)-positive gonadal dysgenesis (including those with *WT1* mutations such as patients with Frasier or Denys–Drash syndromes) and PAIS who have intraabdominal gonads. Intermediate risk is seen in patients with Y chromosome–positive TS and 17β-HSD, with the lowest risk occurring in CAIS, TS without Y material, and OT-DSD with fully differentiated ovarian and testicular tissue.[29,160,176] The optimal management of DSD patients at risk for gonadal tumors is an area of active study. In the past, prophylactic gonadectomy was routinely performed early on; however, experts now recommend a risk-based approach. Given relatively low risk of gonadal malignancy, gonadectomy in patients with CAIS is now typically delayed until after puberty to avoid the need for hormonal replacement for pubertal induction.[136] Abdominal gonads may also be brought to the scrotum or other fixed anatomic position to better allow for active surveillance. Imaging studies and tumor markers may allow for monitoring of those with retained intraabdominal gonads, however, may be insufficient for early detection of precursor lesions. More research is needed to determine the optimal timing and indications for gonadectomy.

Psychosocial Management. The question of gender assignment at birth remains controversial. Although a majority of patients will not experience gender dysphoria, a significant minority may elect to reassign to a different gender.[177]

The assessment of psychosexual development and psychosocial screening is crucial to the overall management of individuals with a DSD and should be performed by experienced mental health professionals. Diagnosis disclosure, peer and support groups, discussions of gender reassignment, and potential anxiety associated with repeated genital examination/medical photography should be part of the overall team management process.

KEY POINTS

- Best management of differences of sex development (DSD) is patient-centered and involves a multidisciplinary team involved in diagnostic steps, clinical evaluation and management, psychosocial support, and shared decision-making. Hormone replacement therapy depends on the underlying diagnosis, gender of rearing, and gender identity. DSD patients with gonads containing Y-chromosome material may be at risk for gonadal malignancy; optimal timing and indication for gonadectomy in at-risk patients requires further study. Genital surgery in DSD patients is an area of controversy.

Summary, 1728

Pubertal development consists of a complex series of interrelated endocrine and physiologic changes that transform a sexually immature individual into a sexually mature one capable of reproduction. Puberty is initiated when gonadotropin-releasing hormone (GnRH) is released in increasing amounts from the hypothalamus, triggering an increase in the secretion of the pituitary hormones luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH and FSH in turn regulate the release of gonadal steroids, which bring about secondary sexual maturation and growth. The increase in sex steroid production by the gonad is referred to as gonadarche. Adrenarche, the increase in adrenal hormone production by the adrenal cortex, is controlled separately but typically precedes gonadarche (though pubarche often follows). A variety of other hormonal and metabolic changes also occur during the pubertal time period (Fig. 102.1), including changes in body composition, sleep, and brain development.

ENDOCRINE PHYSIOLOGY OF SEXUAL MATURATION

Gonadarche

Overview of the Hypothalamic-Pituitary-Gonadal Axis. Pulses of hypothalamic GnRH regulate the secretion of the pituitary gonadotropins LH and FSH. Gonadotropin pulses occur about every 1 to 3 hours in adults and vary with sleep and in response to sex-steroid feedback. This process does not start *de novo* at puberty but is instead based upon preexisting patterns of hormone secretion (Fig. 102.2). In the fetus, hypothalamic GnRH-secreting neurons develop the ability to release pulses of GnRH. GnRH pulse generation operates at a relatively low level for most of the prepubertal period (with the exception of a brief period of activity during infancy) due to active central nervous system (CNS) inhibition. During childhood, there is a waning of inhibition of the pulse generator and an increase in neurostimulatory factors, and GnRH pulses increase in amplitude. These GnRH pulses cause an amplification of gonadotropin pulses, which ultimately result in a rise in gonadal steroids. Pulses increase further during puberty, and the higher levels of gonadal steroids bring about the characteristic physical changes.

Fetal Development. GnRH-secreting neurons arise in the fetal olfactory placode by 5.5 weeks' gestation and migrate to the hypothalamus by 9 weeks' gestation. By 11 to 12 weeks' gestation, the fetal pituitary gland begins secreting FSH and LH, and the fetal hypothalamic-hypophyseal portal system becomes functional. By this time (the end of the first trimester), the arcuate nucleus of the fetal hypothalamus can act as a *GnRH pulse generator* and functionally transduce neural signals into pulsatile GnRH release. The GnRH pulse generator has been well-characterized by studies of pulsatile LH secretion, but mechanistic questions remain.[1] Until recently, the pattern of episodic GnRH secretion was thought to be an intrinsic characteristic of the GnRH neurons. However, GnRH pulse generation is now understood to be driven by kisspeptin production and action.[2] Kisspeptin is secreted from neurons in the anteroventral periventricular nucleus and others known as "KNDy" neurons in the arcuate nucleus that also secrete neurokinin B and dynorphin.

Gonadotropin levels are high in both sexes by midgestation but wane in late gestation, likely due to further development of negative feedback (including the development of gonadal steroid receptors in the hypothalamus and pituitary). Fetal LH and FSH levels are lower in males than in females, likely due to negative feedback from testosterone secreted by the fetal testes.[3] The prenatal rise in testosterone in males is critical for male sexual differentiation.

KEY POINTS

- Pubertal onset is not a *de novo* event, but is instead the continuation of a process that has origins in fetal life. Gonadotropin-releasing hormone secretion is triggered by kisspeptin production and action.

Infancy and Childhood. Neonatal estrogen levels decline rapidly after birth. Subsequently, the newborn hypothalamic-pituitary axis is released from estrogen inhibition, and gonadotropins increase in both amplitude and frequency. In male neonates, the LH pulses result in increased testosterone levels; in female infants, the FSH pulses lead to increased

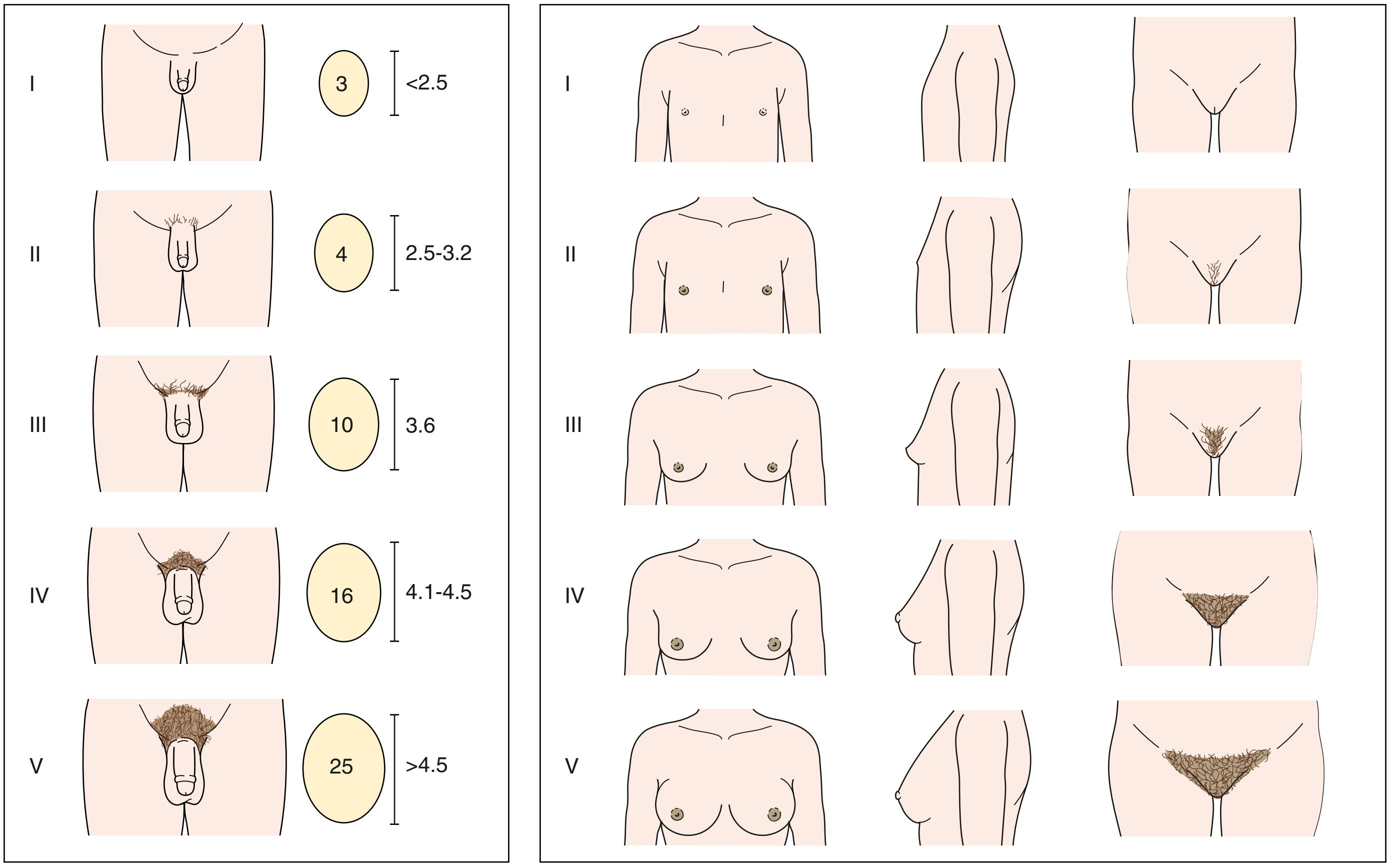

Figure 102.1 **Pubertal stages in boys and girls.** The Tanner staging process describes the pattern of genital and pubic hair development in boys and the pattern of breast and pubic hair development in girls.

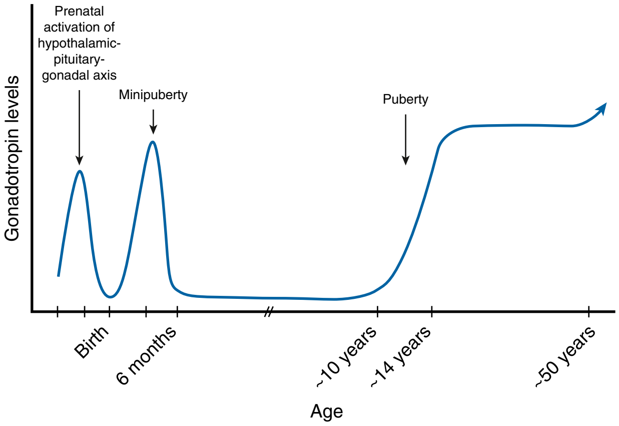

Figure 102.2 **Timeline of changes in the reproductive axis.** Gonadotropin levels are elevated prenatally but decline by late gestation. Levels rise again in infancy ("minipuberty") and then are actively suppressed until the time of pubertal onset.

estradiol. In infant boys, gonadotropins and testosterone levels peak around 1 to 3 months of age and then decline to prepubertal levels by approximately 6 months of age. In girls, gonadotropin and estradiol levels rise and remain high until approximately 6 months, with the exception of FSH, which remains elevated until age 3 to 4 years.[4] This surge of increased gonadotropin and gonadal steroid secretion during infancy is referred to as the postnatal surge, or *minipuberty*.[5]

The high gonadotropin levels of the postnatal surge are associated with rapid expansion of the Sertoli cell population, as well as increases in Leydig and germ cell numbers.[4] This may serve to further prime the LH and FSH response to GnRH later in life. Increased testosterone and dihydrotestosterone (DHT) also appear important for inducing virilization of the male external genitalia (including penile and testicular growth and descent of the testes). In females, the increase in FSH and LH is associated with maturation of the ovarian follicles. The striking sex difference in gonadotropin pulses (with infant females having much higher FSH pulses and infant males having much higher LH pulses) is thought to be due to *in utero* exposure to testicular testosterone in the male fetus.

A lengthy period of quiescence of the hypothalamic-pituitary-gonadal axis follows minipuberty. During this prepubertal juvenile pause, there is active inhibition of the hypothalamic pulse generator. Negative feedback from sex steroids and inhibin contributes to this inhibition, but an intrinsic gonadal steroid-independent CNS mechanism also plays a major role. Notably, gamma-amino butyric acid, the dominant CNS inhibitory neurotransmitter, has been shown to inhibit the hypothalamic pulse generator.[6,7] Increasingly, genetic determinants of this quiescent period have been identified. *MKRN3*, encoding makorin ring finger protein 3, is an imprinted gene that acts to inhibit GnRH secretion during the juvenile pause.[8,9]

The hypothalamic-pituitary-gonadal axis increases further in activity during the peripubertal period, before the physical changes of secondary sexual development are apparent. The mass of hormone secreted during each pulse, and thus the amplitude of each pulse, increases strikingly, suggesting that the sexual-maturation change in LH consists of a specific mass-/amplitude-dependent mechanism. Increased amplitude of LH and FSH pulses (demonstrated by ultrasensitive gonadotropin assays) occurs in most children in midchildhood.[10,11] FSH pulses are less prominent, given the reduced clearance rate of FSH as compared to LH, differences in the factors that modulate the action of GnRH on FSH and LH release by the gonadotrophs, and intrinsic differences in the secretory pattern of the two gonadotropins. LH secretion in early pubertal boys exhibits a diurnal rhythm, with augmentation of pulse amplitude following nocturnal sleep onset.[12-15] Prior to puberty, these low-amplitude and low-frequency pulses are unable to activate gonadal function. As puberty progresses, there is continued augmentation of the LH pulses. The full adult pattern, whereby there is no diurnal rhythm in LH pulse amplitude, does not occur until adulthood.[12] Thus, the increased nocturnal activity of the GnRH pulse generator appears to represent a discrete developmental stage.

A diurnal rhythm of testosterone secretion also exists in peripubertal boys. Testosterone declines gradually in the early part of the night, followed by a postmidnight increase reflecting the nocturnal onset of LH pulsatility.[16] Peak levels of serum testosterone occur in the early morning, with lowest values in the late evening. The delay of approximately 60 minutes between the LH peak and the testosterone peak is presumably due to the time required for synthesis and secretion of testosterone.[17] In prepubertal girls, a diurnal rhythm of testosterone is also seen with augmentation in the early morning. Estradiol also has a diurnal rhythm, with higher values in the early morning in late prepubertal and early pubertal girls.[11]

KEY POINTS

- There is a surge of gonadotropin and gonadal steroid secretion during infancy (referred to as minipuberty), followed by a lengthy period of quiescence of the hypothalamic-pituitary-gonadal axis (the "juvenile pause"). During later childhood, gonadotropin-releasing hormone (GnRH) pulses increase in amplitude. These GnRH pulses cause an amplification of gonadotropin pulses.

Puberty. As puberty approaches, GnRH pulses increase further in amplitude. In response, there is increased amplitude of gonadotropin pulses and increased daytime secretion of LH and FSH. The frequency of these pulses increases slightly as well, which may contribute to making the gonadotrophs more sensitive to pulses of GnRH.[12] Increasing pituitary responsiveness to GnRH can be demonstrated pharmacologically by administration of exogenous GnRH; exogenous GnRH is relatively ineffective in stimulating gonadotropin or gonadal steroid secretion prior to puberty but becomes effective after pubertal onset. If gonadotrophs are exposed to continuous rather than episodic GnRH, the GnRH receptors are downregulated, with decreased responsiveness to GnRH. This phenomenon occurs when GnRH agonists are utilized to treat central precocious puberty (CPP).

During puberty, urinary FSH rises 5-fold in both sexes. In girls, FSH rises in the early stages of puberty, whereas LH rises in the later stages. Urinary LH rises 100-fold in girls and 50-fold in boys; the rise in first morning voided urinary LH levels precedes the physical onset of puberty.[18,19] Qualitative changes in gonadotropins occur in addition to these quantitative ones; glycosylated variants of FSH and LH have distinct signaling properties and provide an additional regulatory mechanism.[20]

In boys, circulating LH activates membrane-bound LH receptors in Leydig cells to stimulate testosterone secretion. The enzyme 5-alpha reductase in certain tissues converts testosterone to DHT, which is a more potent activator of the androgen receptor. The testes additionally secrete other sex steroids, including androstenedione, delta-5-androstenediol, dihydrotestosterone, and relatively small amounts of estradiol. Testosterone rises throughout puberty, with the steepest increase in testosterone levels occurring between pubertal stage 2 and 3 (Fig. 102.1). In boys, FSH supports spermatogenesis by binding to the FSH receptor on the cellular membrane of the seminiferous tubules. Nearly all estrogen in males is converted from testicular and adrenal androgens such as androstenedione by the enzyme aromatase. In all stages of puberty (Fig. 102.1), boys have lower estrogen levels than girls. Estradiol in males is a more potent inhibitor of gonadotropin secretion than testosterone.

In girls, extraglandular conversion of ovarian and adrenal androstenedione gives rise to nearly all the circulating testosterone. FSH binds to cell-surface receptors on ovarian follicular cells to influence follicular development and stimulate estrogen secretion. The ovary produces most of the estradiol in females, although a small fraction arises from extraglandular conversion of testosterone and androstenedione by aromatase. Girls have higher estradiol concentrations than boys prior to puberty, with a rise through puberty until the pubertal growth spurt and a decrease thereafter. This results in more advanced levels of skeletal maturation in girls compared with boys, as it is estrogen that determines the acceleration of bone elongation during puberty, and eventually epiphyseal closure.

In prepubertal girls, small amounts of estrogen will suppress gonadotropin secretion. After midpuberty, estrogen can either stimulate or suppress gonadotropin release, depending on the estrogen level and pattern. Estrogen has an inhibitory effect on FSH and LH secretion early in the menstrual cycle. The onset of positive feedback (whereby higher amounts of estrogen can stimulate GnRH and gonadotropin release) occurs at midcycle once the ovarian follicle is of adequate size to produce enough estrogen and the pituitary has enough readily releasable LH to cause an LH surge (see Chapter 117). The LH surge stimulates prostaglandin, which causes ovulation via an inflammatory response in the dominant follicle. The corpus luteum forms from the remnants of the dominant follicle and produces progesterone, which prepares the endometrium for implantation and pregnancy. The increased estrogenic activity of the midcycle ovary stimulates growth of the endometrium, but the decrease in estrogen and progesterone toward the end of the menstrual cycle leaves the endometrium with no endocrine support. This, in addition to the local action of prostaglandins and constriction of arterioles, leads to endometrial necrosis and menstrual bleeding.

KEY POINTS

- Puberty is initiated when gonadotropin-releasing hormone is released in increasing amounts, triggering an increase in the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). LH and FSH in turn regulate the release of gonadal steroids (testosterone and estradiol), which bring about secondary sexual maturation and growth.

Adrenarche

The pubertal increase in adrenal androgens (principally dehydroepiandrosterone [DHEA] and its sulfate dehydroepiandrosterone sulfate [DHEAS]) is known as *adrenarche*. The increase in these hormones leads to the physical findings of increased growth of axillary and pubic hair (known as *pubarche*) (Fig. 102.1), as well as body odor, increased sebaceous gland activity, and acne. DHEA and DHE-S are very weak agonists for the androgen receptor, and their androgenic potency is principally derived from peripheral conversion to testosterone and DHT. Clinically, DHEAS is a more useful measurement than DHEA, due to its significantly longer half-life.

During fetal development and early infancy, the adrenal gland consists of separate fetal and adult zones.[21] The fetal zone secretes large amounts of DHEAS due to minimal expression of the enzyme

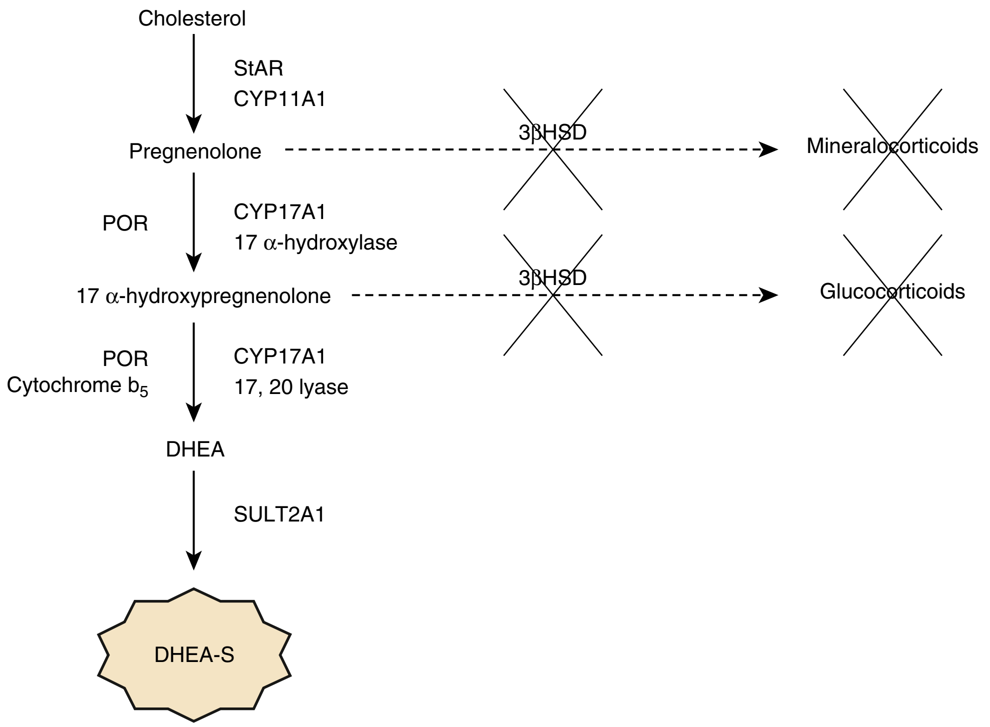

Figure 102.3 **Dehydroepiandrosterone sulfate (DHEAS) production by the zona reticularis of the adrenal glands.** DHEAS production is driven by expression of steroidogenic acute regulatory protein (StAR), cytochrome P450scc (CYP11A1), 17α -hydroxylase/17,20-lyase (CYP17A1), and DHEA sulfotransferase (SULT2A1), along with cofactors cytochrome P450 reductase (POR) and cytochrome b_5. The 17,20-lyase activity of CYP17A1 is enhanced by cytochrome b5. The lack of 3βHSD expression ensures that precursors are not diverted to the mineralocorticoid and glucocorticoid pathways.

3β-hydroxysteroid dehydrogenase, which if expressed at higher levels would direct steroidogenesis toward the mineralocorticoid and glucocorticoid pathways. Regression of the fetal zone in early infancy via apoptosis results in a fall in DHEAS levels. Thereafter, levels stay low until the onset of adrenarche. Differentiation of the adult zone and formation of a continuous zona reticularis results in an increase in DHEAS starting around 6 years of age (roughly 2 years prior to the onset of increased gonadal steroid secretion). The activities of cytochrome P450scc (CYP11A1), 17α-hydroxylase/17,20-lyase (CYP17A1), and DHEA sulfotransferase (SULT2A1), all of which are abundant in the zona reticularis, direct steroidogenesis toward the production of DHEAS (Fig. 102.3).[22] In addition, DHEAS production is increased by expression of cofactor proteins such as cytochrome b5 and cytochrome P450 oxidoreductase, which enhance the activity of CYP17A1. DHEA and DHEAS levels are higher in males than in females and continue to rise in both sexes into the second decade of life (Fig. 102.4).

While certain hormones have been found to help regulate adrenarche, the trigger for its onset remains elusive. Pituitary adrenocorticotropic hormone (ACTH) is necessary, and absence of adrenarche is noted in patients with ACTH receptor mutations and in those with ACTH deficiency.[23,24] However, the relative potency of ACTH to control adrenal androgen versus cortisol secretion is much less, by a factor of approximately 1000. Furthermore, ACTH levels do not rise at the time of adrenarche, indicating that other factors are involved.

KEY POINTS

- The pubertal increase in adrenal androgens (primarily dehydroepiandrosterone and dehydroepiandrosterone sulfate) is known as adrenarche. An increase in these hormones leads to the physical findings of axillary and pubic hair growth, body odor, increased sebaceous gland activity, and acne.

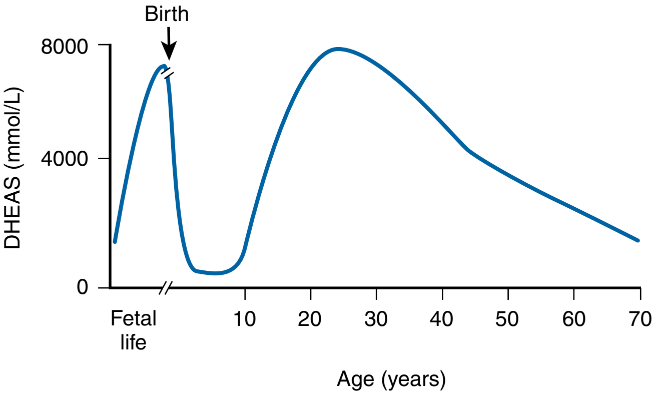

Figure 102.4 **Variation in circulating dehydroepiandrosterone sulfate (DHEAS) concentration through human life.** DHEAS concentrations reach a peak at term; following birth, there is a rapid decline. At approximately 6 years of age, DHEAS concentrations rise again (adrenarche) and reach a peak during early adulthood, declining thereafter in a process often called adrenopause. (From Auchus RJ, Rainey WE. Adrenarche: Physiology, biochemistry and human disease. *Clin Endocrinol (Oxf).* 2004; 60:288–296.)

CONTROL OF THE ONSET OF PUBERTY

Genetics of Pubertal Onset

Pubertal onset involves a complex interplay of inhibitory and stimulatory factors, and numerous genes and regulatory signals are critical to the process. To date, approximately 50 genes have been implicated in patients who fail to progress through puberty normally due to hypogonadotropic hypogonadism,[25] whereas only four monogenic causes of CPP have been identified (including mutations in *KISS1*, *KISS1R*, *MKRN3*, and *DLK1*) (also see Chapter 103).

KISS1 and KISS1R. As previously noted, kisspeptin neurons in the arcuate nucleus function as the hypothalamic pulse generator. Kisspeptin, encoded by *KISS1*, is a critical stimulatory factor for GnRH secretion and functions as a gatekeeper of pubertal onset. Inactivating or loss-of-function mutations in *KISS1* and in the gene encoding G protein–coupled kisspeptin receptor (*KISS1R*, previously *GPR54*) are associated with hypogonadotropic hypogonadism and pubertal delay.[26-28] Alternately, gain-of-function mutations in *KISS1* and *KISS1R* have been identified as causes of CPP. An autosomal dominant *KISS1R* mutation causing prolonged activation of intracellular signaling pathways in response to kisspeptin is associated with CPP.[29] A missense mutation in *KISS1* leading to prolonged kisspeptin effect has also been identified in a 1-year-old male with CPP.[30]

Makorin Ring Finger Protein 3 (MKRN3). *MKRN3* is an imprinted gene located on chromosome 15q11-q13 in the Prader–Willi syndrome region.[9] MKRN3 acts to inhibit GnRH secretion during the juvenile pause and has been described as imposing a neurobiologic break on puberty.[31] The maternal *MKRN3* allele is not expressed, due to imprinting; a paternally inherited loss-of-function mutation of *MKRN3* leads to deficiency of *MKRN3* and autosomal dominant CPP,[8,32] though the precise mechanism by which this occurs is unknown. To date, *MKRN3* mutations are the most commonly identified genetic cause of CPP. Mutations in *MKRN3* are particularly common in boys and in familial cases, though affected girls typically have an earlier age at pubertal onset (median age 6.0 vs. 8.5 years).[33]

Tachykinin Precurson 3 (TAC3) and TAC3R/Neurokinin B. Neurokinin B (NKB), encoded by *TAC3*, also appears to play an important role in puberty initiation via stimulatory effects on kisspeptin release in the arcuate nucleus.[34] Mutations in both *TAC3* and the gene encoding the NKB receptor, *TAC3R*, have been shown to result in failed GnRH release and hypogonadotropic hypogonadism.[35,36] Mutations in the NKB system are now thought to occur in more than 5% of patients with normosmic idiopathic hypogonadotropic hypogonadism.[37]

Delta-Like Noncanonical Notch Ligand 1 (DLK1). Like *MKRN3*, *DLK1* is a paternally expressed imprinted gene that appears to play a role in pubertal onset, though mutations in *DLK1* occur much less frequently than in *MKRN*3. Paternally inherited *DLK1* deletions were found through linkage analysis and whole-genome sequencing in multiple individuals with CPP within the same family.[38] *DLK1* is thought to affect GnRH secretion through the regulation of kisspeptin.

Timing of Puberty

Secular Trends and Ethnic Differences. Pubertal timing describes the pubertal status of a child in relation to same-sex and same-age peers. It is determined largely by genetic factors and is modulated by both intrinsic and environmental factors (including the intrauterine environment, nutritional status, and metabolic stress). Direct genetic effects account for 50% to 80% of the variation of timing of puberty in healthy populations.[39-42] Recently, genome-wide association studies have been used to identify genetic loci that affect pubertal timing, including a 2017 analysis of more than 360,000 women.[43]

Sexual maturation in girls and boys has occurred at younger ages throughout the past 100 years. Between 1850 and 1950, the mean age of menarche decreased by 3 to 4 months each decade in industrialized nations.[44] Most investigators believe that improved nutritional status and improving health conditions worldwide account for most of these changes. An expert panel review of data collected between 1940 and 1994 also reported a decrease in the age of menarche by several months over the past 25 years.[45] These more recent pubertal trends are likely due to the increased prevalence of childhood obesity in this country as well as environmental influences[45] (see later).

Changes in the age of onset of thelarche have been more difficult to characterize, as methods have varied across studies, and some analyses have been limited by small sample sizes. However, a large cross-sectional study of 17,000 girls suggested that thelarche has advanced in the second half of the twentieth century.[46] These data are supported by a relatively recent Danish study, which showed significantly earlier onset of thelarche in a 2006 cohort of girls as compared with a 1991 cohort.[47] Progression of breast development after onset through later stages is not clearly accelerating, however.[45]

There is considerable variability in the age of pubertal events among ethnic groups. Black girls often have pubic hair development prior to the onset of breast development, while the opposite is typically true for White girls.[46] In the United States, the ages of thelarche, menarche, and onset of pubic hair development are all significantly younger in Black girls as compared with non-Hispanic White and Mexican American girls.[48,49] In a relatively recent large longitudinal study, mean ages of breast stage 2 development were 8.8 years for Black girls, 9.2 years for Hispanic girls, 9.6 years for non-Hispanic White girls, and 9.9 years for Asian girls.[50] Data from the longitudinal Bogalusa Heart Study has shown advancement in the age of menarche in White and Black American girls from 1974 to 1994, with the timing advancing more in Black American girls as opposed to White girls.

In general, the timing of thelarche varies more than the timing of menarche. There appears to be a physiologic compensation for puberty that occurs in the early-normal age range, such that girls with thelarche at age 9 years have an average of 2.7 years to menarche, whereas girls with thelarche at age 13 years have an average of 0.7 years to menarche.[51]

In boys, data quality issues make drawing conclusions about secular trends even more difficult. Though some studies have suggested earlier genital development in more recent decades, data are insufficient to conclude this with certainty.[45] As in girls, there are significant ethnic differences with respect to ages of attainment of various pubertal stages.[49,52]

KEY POINTS

- Changes in the age of onset of puberty over recent decades are difficult to characterize, as methods have varied widely across studies. However, evidence points toward younger ages of attainment of both thelarche and menarche in girls. There is variability in the age of pubertal events among ethnic groups.

Nutrition. The pronounced physical changes of puberty require significant energy input, and thus energy status unsurprisingly has a critical regulatory effect on pubertal timing (Fig. 102.5). The metabolic hormone leptin is secreted by adipocytes in concentrations that are highly associated with fat mass, acting as an essential permissive signal that ensures the availability of adequate energy stores prior to entrance into puberty.[53] Appropriate leptin concentrations are required for maturation of the hypothalamic-pituitary-gonadal axis, pubertal progress and gonadal function.[54] Once bound to its receptor, leptin helps promote a feeling of satiety. Leptin deficiency, due to homozygous mutations in the leptin (*LEP*) or leptin receptor (*LEPR*) genes, results in hypogonadotropic hypogonadism and early-onset obesity due to lack of

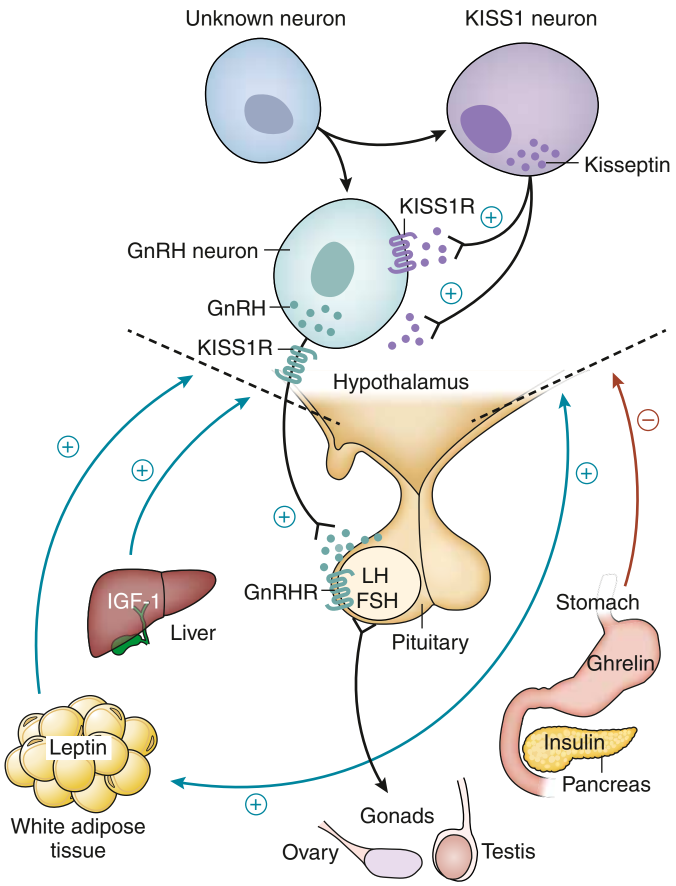

Figure 102.5 **Tentative model for the metabolic control of GnRH secretion by peripheral metabolic hormones.** The peripheral hormones that transmit metabolic signals to GnRH neurons are shown. Leptin, a signal for energy abundance, is a permissive factor for GnRH secretion. Ghrelin, a putative signal of energy insufficiency, is an inhibitory factor for GnRH secretion. Insulin and IGF1 have stimulatory effects on the reproductive axis. Dashed line represents proposed pathway. *FSH*, Follicle-stimulating hormone; *GnRH*, gonadotropin-releasing hormone; *GnRHR*, gonadotropin-releasing hormone receptor; *IGF1*, insulin-like growth factor 1; *KISS1*, kisspeptin; *KISS1R*, kisspeptin receptor; *LH*, luteinizing hormone; *+*, stimulatory effect; *–*, inhibitory effect. (Reprinted with permission from Elsevier. From Abreu AP, Kaiser UB. Pubertal development and regulation. *Lancet Diabetes Endocrinol.* 2016 Mar;4(3):254–264.)

satiety.[55-57] In leptin-deficient patients, there is initiation or resumption of gonadotropin secretion after leptin replacement. Recombinant leptin also restores gonadotropin secretion in women with hypothalamic amenorrhea associated with anorexia nervosa,[58] although is not commonly used, due to limited supply of recombinant leptin.

Ghrelin, the ligand of the growth hormone (GH) secretagogue receptor 1a or ghrelin receptor, is secreted in response to food deprivation and plays a role in signaling negative energy balance.[59] Release of ghrelin from the enteroendocrine cells of the gastrointestinal tract results in the feeling of hunger that results in food intake. Ghrelin decreases GnRH secretion and has an overall inhibitory effect on the gonadotropic axis,[60] consistent with its role as an indicator of insufficient energy. Insulin also appears to modulate GnRH secretion and likely has additional effects on pubertal onset via stimulation of leptin secretion.[61,62]

Recent work has shed light on the process by which metabolic signals (including mammalian target of raptomycin [mTOR], AMP-activated protein kinase [AMPK], and SIRT1) modulate pubertal timing via effects on kisspeptin production in kisspeptin neurons (Fig. 102.6). mTOR is activated in conditions of energy excess and helps mediate the permissive effects of leptin on pubertal onset.[63] AMPK, a major cellular energy sensor, is inhibited by leptin and has a restrictive effect on *KISS1* expression in conditions of negative energy balance.[64] *SIRT1* is a nuclear protein expressed in kisspeptin neurons and restrains female puberty by decreasing *KISS1* promoter activity.[65] As puberty approaches, *SIRT1* is expelled from the KISS1 promoter, which helps permit *KISS1* expression. Overnutrition accelerates these changes, enhancing the expression of *KISS1* and advancing puberty.[65] Undernutrition, in contrast, increases levels of *SIRT1* and delays puberty.

Obese girls have a clear trend toward earlier puberty, and it appears that boys likely do as well.[66,67] Lee et al. followed young girls longitudinally and found that higher body mass index (BMI) z-scores in early childhood and higher rates of BMI change between early and midchildhood are associated with earlier thelarche, suggesting that childhood obesity in the United States may decrease the age of onset of puberty for US girls.[68] Conversely, low body fat, as occurs in anorexia and some avid adolescent female athletes, has long been thought to postpone menarche.[69] It is postulated that local production of estrogen by adipose tissue may account for earlier breast development in obese girls, but this has not been consistently shown.[70]

KEY POINTS

- The pronounced physical changes of puberty require significant energy input, and thus energy status has a critical regulatory effect on pubertal timing. Metabolic signals modulate pubertal timing via effects on kisspeptin production.

Endocrine-Disrupting Substances. Though genetic factors play the greatest role in the determination of pubertal timing, endocrine-disrupting compounds (EDCs) are potential contributors to observed shifts. EDCs are exogenous compounds that disrupt endogenous endocrine activity via effects on hormone synthesis, metabolism, or elimination (see Chapter 137). Although EDC exposure has been typically thought to lead to earlier pubertal development, several studies suggest later pubertal development (or earlier onset but overall longer time to maturation).[71] As one example, phenols, including bisphenol A, and phthalates have gained attention in recent years for their estrogenic and antiandrogenic properties, respectively.[72] In a large study of 1051 girls, higher 2,5-dichlorophenol was associated with earlier menarche by 7 months, and mono-3-carboxypropyl phthalate was associated with later thelarche and menarche.[73] Other smaller studies have also shown possible effects of phthalates and phenols on pubertal timing.[74-76] Additional compounds, including flame retardants/polybrominated diphenyl ethers, polychlorinated biphenyls, and dioxins, have all been associated with alterations in pubertal timing. Effects appear to depend upon the timing, duration, and degree of exposure, as well as on the specific compound and gender of the child.[71]

PHYSICAL CHANGES OF PUBERTY

Physical development of puberty can be denoted by sexual maturation ratings, commonly called Tanner stages. These standards allow for objective descriptions of pubertal progress.

Boys

Table 102.1 describes the sequence of pubertal genital changes in boys. The first sign of central puberty in boys is typically an increase in the size of the testes to over 2.5 cm in the longest diameter (excluding

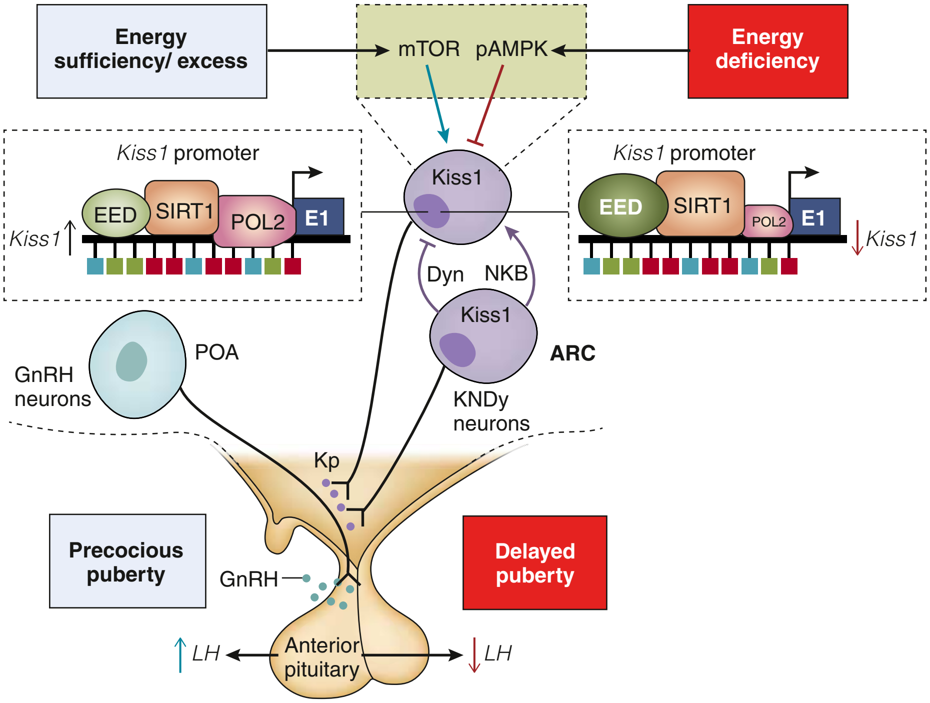

Figure 102.6 **Metabolic regulation of gonadotropin secretion.** The mTOR pathway is activated in conditions of energy excess. This leads to eviction of SIRT1 and EED from the *KISS1* promoter, which enhances Kiss1 expression and stimulates gonadotropin secretion. Alternately, the AMPK pathway is activated in energy-deficient conditions. This is associated with the continued presence of SIRT1 and EED, leading to suppression of Kiss1 expression and reduced gonadotropin secretion. *ARC*, Arcuate nucleus; *NKB*, neurokinin B; *Dyn*, dynorphin; *KNDy*, Kiss1, NKB, and Dyn; *EED*, embryonic ectoderm development; *mTOR*, mammalian target of raptomycin; *AMPK*, AMP-activated protein kinase. (From Vazquez MJ, Velasco I, Tena-Sempere M. Novel mechanisms for the metabolic control of puberty: implications for pubertal alterations in early-onset obesity and malnutrition. *J Endocrinol.* 2019;242:R51–R65.)

the epdidymus), equivalent to a testicular volume of 4 mL or greater. Increasing testicular size early in puberty occurs due to an increase in Sertoli cell number and seminiferous tubule length (stimulated by FSH). Rising testosterone levels result in enlargement of the penis, and scrotal thinning occurs. Pubic hair development occurs as a result of adrenal and testicular androgen secretion and again is classified separately from genital development (Table 102.2). The appearance of spermatozoa in early morning urinary specimens (spermarche) occurs at a mean chronologic age of 13.4 years; this usually occurs at gonadal stages 3 to 4 and pubic hair stages 2 to 4.

Increasing testosterone concentrations (or the metabolic products of testosterone) additionally produce changes in nonreproductive organs. The larynx increases in size and the voice deepens, red blood cell mass increases, high-density lipoprotein levels decline, and body

TABLE 102.2 Stages of Pubic Hair Development in Boys

Pubertal Stage	Description	Median Age (Years)	Age at 2.3 Percentile (Years)
1	No pubic hair.		
2	Sparse growth of long, slightly pigmented, downy hair (straight or slightly curled), appears chiefly at the base of the penis.	11.3	8.3
3	Hair is considerably darker, coarser, and mostly curled. Hair spreads sparsely over the pubic junction.	12.0	10.0
4	Hair is adult in type and distributed as an inverse triangle without spread to the medial surface of the thighs.	13.2	11.1
5	Hair is adult in quantity and type and distributed as an inverse triangle with spread to the medial surface of the thigh.	15.0	12.2

A description of each stage is shown, along with median age at each pubertal stage and age at the 2.3 percentile (approximates –2 standard deviations).
Data from the National Health and Nutrition Examination Survey III.

TABLE 102.3 Stages of Breast Development in Girls

Pubertal Stage	Description	Ethnicity	Median Age at Entry (Years)
1	Preadolescent; only the papilla is elevated.	n/a	
2	Breast bud stage; the breast and papilla are elevated as a small mound. Areolar diameter is enlarged.	Non-Hispanic White	10.38
		Non-Hispanic Black	9.48
		Mexican American	9.80
3	Further enlargement of breast and areola has occurred, with no separation of their contours.	Non-Hispanic White	11.75
		Non-Hispanic Black	10.79
		Mexican American	11.43
4	The areola and papilla project to form a secondary mound above the level of the breast.	Non-Hispanic White	13.29
		Non-Hispanic Black	12.24
		Mexican American	13.07
5	Mature stage; only the papilla projects because of recession of the areola to the general contour of the breast.	Non-Hispanic White	15.47
		Non-Hispanic Black	13.92
		Mexican American	14.70

A description of each stage is shown, along with median age of attainment of each stage.
(Ethnicity data from Sun SS, Schubert CM, Chumlea WC, et al. National estimates of the timing of sexual maturation and racial differences among US children. *Pediatrics*. 2002;110:911–919.)

hair (including facial hair) increases. Through the ensuing years, hair recedes on the scalp. Testosterone or estradiol produced from testosterone in the nervous system stimulates sexual libido, and behavior changes. Maturation takes many years; for example, although adult testosterone concentrations in blood are reached by age 15 or so, growth of the adult male beard is not usually complete until 20 to 25 years of age.

KEY POINTS

- The first sign of central puberty in a boy is an increase in size of the testes. Increasing testosterone levels result in changes in the genitalia, as well as in nonreproductive organs.

Girls

The first sign of puberty in the female is an increase in linear growth velocity, although breast development is usually detected first. Breast growth is stimulated by ovarian estrogen secretion and occurs in a predictable sequence, with eventual size and shape influenced by genetic and nutritional factors (Table 102.3). Likewise, areolar changes in size, color, and erectility occur in a predictable order. Increasing estrogen levels additionally lead to enlargement of the labia minora and majora. The prepubertal vaginal mucosa is reddish (though not bright red as might be found with an infection) and progresses to a duller pinkish color with clear or slightly whitish discharge due to estrogen stimulation. The ovaries enlarge, the uterus enlarges, and the fundus becomes prominent.[77] Sonographic standards are available; uterine volume greater than 1.8 mL and ovarian volume greater than 1.2 mL occur in CPP or normal puberty. Pubic hair development in girls is determined chiefly by adrenal and ovarian androgen secretion (Table 102.4). The relative timing of growth and pubertal changes in boys and girls is summarized in Fig. 102.7.

Menarche occurs in midpuberty, approximately 2.5 years after the onset of breast development. In a recent longitudinal study of 946 girls, the median age of menarche was 12.25 years.[78] Compared with Black participants (median age of menarche 12.0 years), Hispanic girls were more likely to have menarche earlier (11.83 years), whereas White and Asian girls were more likely to have menarche later (12.67 and 12.75 years, respectively).

KEY POINTS

- The first sign of puberty in the female is an increase in linear growth velocity, although breast development is usually detected first. Menarche occurs at an average age of 12.25 years.

TABLE 102.4 Stages of Pubic Hair Development in Girls.

PUBERTAL GROWTH AND THE GROWTH HORMONE/INSULIN GROWTH FACTOR AXIS

There is a close interplay between the gonadal steroids and GH during pubertal development. During puberty, increasing gonadal steroid concentrations stimulate the GH/insulin-like growth factor (IGF) axis and enhanced secretion of GH in both the basal and stimulated state occurs. Likewise, IGF1 acts synergistically with the gonadotropins to stimulate gonadal steroid synthesis. Thus, increasing levels of both GH and the gonadal steroids result in coordinated anabolic effects on growth, and it appears that GH modulates the timing of sexual maturation.[79] As such, children with GH deficiency have delayed pubertal onset and a lower overall rate of pubertal development, though they do not entirely fail to undergo pubertal changes.

Mean growth velocity is approximately 6 cm/year during prepubertal childhood. As a result of increases in GH/IGF1 and the rising gonadal steroid levels, growth velocity increases in girls at 11 years of age, peaking on average at age 12 years (Tanner stage 2–3). In boys, growth velocity increases later, beginning at approximately 13 years and peaking at approximately 14 years of age (Tanner stage 3–4) (Fig. 102.8). The mean 24-hour concentration of GH is approximately 5 to 7 µg/L in prepuberty and early puberty and increases strikingly during middle to late puberty to approximately 13 to 15 µg/L. The rise in the mean GH concentration is caused primarily by increases in pulse amplitude and an increase in the mass of the GH pulse secretory burst rather than by changes in pulse frequency.[80,81]

KEY POINTS

- Increasing levels of growth hormone and the gonadal steroids together result in coordinated anabolic effects on growth during puberty.

ADDITIONAL CHANGES DURING SEXUAL MATURATION

Changes in Body Composition and Bone Mineral Density

Gender differences in body composition before puberty are modest compared with postpubertal differences. Throughout infancy, females have a slightly greater percent body fat than males.[82,83] In early childhood, males and females have comparable absolute fat mass and fat free mass. By later childhood, girls begin to gain fat more readily, and by

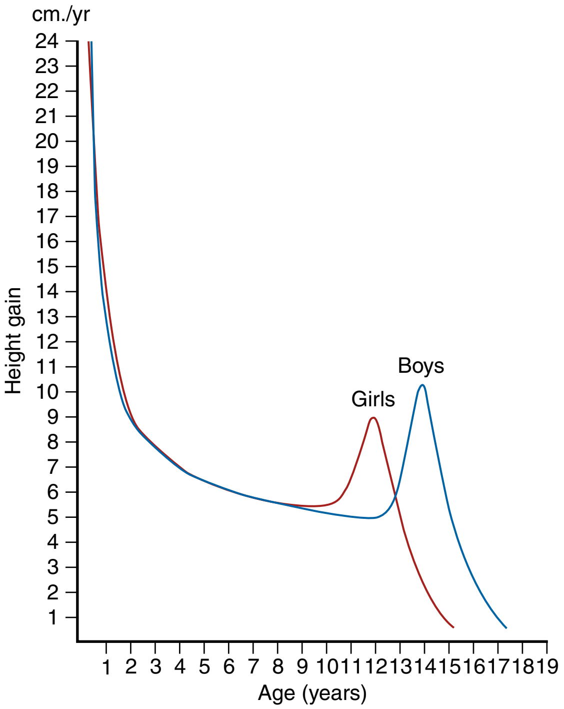

Figure 102.8 **Typical individual curves for height velocity in boys and girls.** Peak height velocity during puberty occurs on average at age 12 years in girls and age 14 years in boys. (From Tanner JM, Whitehouse RH, Takaishi M. Standards from birth to maturity for height, weight, height velocity, and weight velocity: British children, 1965. *Arch Dis Child.* 1966; 41:454–471.)

10 years of age, girls have approximately 2 kg more fat mass than boys. Meanwhile, boys gain slightly more fat free mass.[83-85] During puberty, girls gain significantly more fat mass than males and by the end of puberty, have approximately 5 to 6 kg more absolute fat mass. Males do not significantly change their absolute fat mass during puberty. By approximately age 12 years, fat free mass gain in females begins to plateau, and males begin gaining fat free mass at an increased rate.[84] By adulthood, males have 20 kg greater fat free mass than females on average. The net effect of these changes is a decreasing percent body fat throughout puberty in males to an adult value of approximately 13%. In females, the net effect of a plateau in fat free mass and increasing fat mass results in a higher percent body fat of approximately 25%.

In female adolescents, the hips enlarge and the waist-to-hip ratio decreases with advancing pubertal stage.[86] Females generally have gynecoid body fat distribution, with fat centered around the hips and thighs, whereas males have an android body fat distribution, with fat distributed mainly in the abdominal area. In males, the android shape develops primarily during puberty. Females remain gynecoid (though become more so) during puberty, but proportions change toward a more android shape in later life, after menopause, or with increasing parity or with the hyperandrogenic ovulatory disorder polycystic ovarian syndrome (see Chapter 124).

The most important phases of bone accretion occur during infancy and during puberty.[87] Girls reach peak calcium accretion around 12.5 years of age, while boys reach this stage at approximately 14 years. Approximately one-fourth of total skeletal calcium is laid down during the 2 peak pubertal years of bone growth.[88] A significant reduction in bone mass accrual occurs in females after 15 years of age (2–4 years after menarche), while bone mass in males continues to increase between 15 and 18 years of age.[89] In girls, later age at menarche is associated with low bone mineral density and higher fracture risk, likely due to lower peak bone mass.[90-92]

Sex steroids are critical for bone maturation, and hypogonadism in both sexes leads to osteoporosis. Males with aromatase deficiency or estrogen receptor defects have tall stature, unfused epiphyseal cartilages, and reduced bone mineral density/osteoporosis. These men have helped identify estradiol as critical for attainment of normal bone mineral density and epiphyseal fusion.[93] Although estrogen plays the critical role in stimulating new bone formation, augmenting mineralization, promoting epiphyseal maturation, and establishing normal skeletal proportions, androgens also contribute. In addition, GH and IGF1 are required for attainment of peak bone mass.[84,94] Ethnicity and other genetic effects may account for up to 11% of the variation in bone mineral density.[95]

Changes in Sleep and Brain Development

Changes in sleep regulation occur during sexual maturation, and these changes may actually precede the physical changes of puberty.[96] The body's circadian rhythm is driven by a circadian pacemaker in the hypothalamic suprachiasmatic nucleus (SCN), which is genetically regulated but directly influenced by environmental cues such as light. Changes to circadian rhythm during adolescence result in later sleep onset, later wake times (when children are unrestrained by school schedules), and less overall sleep. At nighttime, melatonin production in the SCN promotes sleep onset; this secretion pattern becomes later as children progress though the stages of puberty.[97] Sleep electroencephalogram patterns change during puberty and may account for the marked daytime sleepiness of adolescence, regardless of overall sleep time. Notably, the large, slow ("delta") waves of non-rapid eye movement (NREM) sleep decline significantly during adolescence, though the proportion of NREM to rapid eye movement sleep remains the same.[98] A greater tolerance for sleep deprivation additionally occurs during the maturation process.

There are considerable differences in the cognitive abilities of children versus adults, and much of this change occurs during adolescence. The prefrontal cortex, an area of the brain concerned with forward planning and regulatory control of emotional behavior, continues to develop until the age of 20 to 25 years. Magnetic resonance imaging studies of the adolescent brain demonstrate specific structural changes during puberty. There is a linear increase in white matter due to increased myelination between ages 4 and 22 years, with males showing steeper increases in volume as compared with females.[99-102] Alternately, gray matter volumes change in a region-dependent nonlinear (inverted U-shaped) manner, with peak gray matter volume occurring 1 to 2 years earlier in females than in males.[99,102] A reduction in cortical synaptic density and neuronal density occurs secondary to synaptic pruning, which is more prominent in males compared with females.[101] Gender differences in brain structure likely reflect gonadal steroid influences on brain growth and remodeling.

Brain plasticity decreases during puberty, as evidenced by greater difficulties with foreign language acquisition in adults compared with prepubertal children and improved traumatic brain injury outcomes in young children compared with older teens or adults. Mental illnesses such as mania, depression, obsessive-compulsive disorder, and schizophrenia are all more common after puberty. This increase is postulated to be related to pubertal changes in brain architecture and function.

KEY POINTS

- Fat and fat free mass changes during puberty result in adult males having a much lower percent body fat than adult females (13% vs. 25%). A critical phase of bone accretion occurs during puberty, with peak calcium accretion around 12.5 years of age in girls and 14 years in boys. Changes in sleep regulation also occur, and these changes may precede the physical changes of puberty.

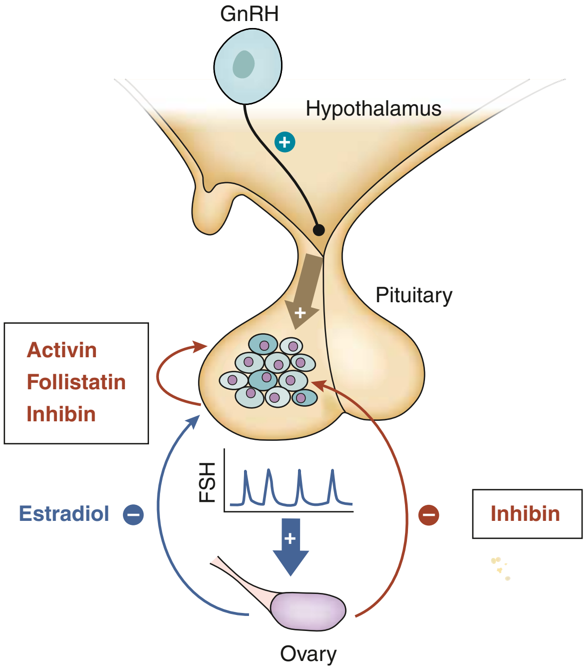

Figure 102.9 Regulation of follicle-stimulating hormone (FSH) secretion by inhibin, activin, and follistatin in females. Gonadotropin-releasing hormone pulses are transported to the anterior pituitary by portal vasculature to stimulate FSH synthesis and secretion by gonadotrope cells. At the anterior pituitary level, a local loop involving activin, inhibin, and follistatin regulates FSH secretion in an autocrine/paracrine fashion. At the ovarian level, estradiol and inhibin are two key negative feedback regulators of FSH secretion. While the ovary also produces activin and follistatin, these hormones are not believed to play an endocrine role in controlling FSH secretion. (From Padmanabhan V, Cardoso RC. Neuroendocrine, autocrine, and paracrine control of follicle-stimulating hormone secretion. *Mol Cell Endocrinol.* 2020;500:110632.)

Other Changes at Puberty

Follicle-Stimulating Hormone Regulatory Proteins: Inhibin, Activin, and Follistatin. Inhibin, produced by multiple tissues, including the ovarian granulosa cells and testicular Sertoli cells, acts to suppress FSH release from the pituitary (Fig. 102.9). Inhibin B rises twice during male development, reflecting the two periods of Sertoli cell proliferation in infancy and in early puberty. In the early stages of male puberty, inhibin B values have a close positive relationship to LH and testosterone levels and increase with pubertal progression. In genital stage 3 (characterized by continued testicular enlargement), inhibin B values peak and instead become inversely related to FSH levels[103,104]; this relationship with FSH persists into adulthood. During childhood, inhibin B is a useful diagnostic marker for the presence and function of Sertoli cells, and thus testicular tissue, in males. In girls, serum levels of inhibin A and B increase in early puberty, and there is a strong positive correlation between inhibin B and FSH and estradiol early in puberty. After pubertal stage 2, these relationships diminish.[105] Inhibin B is predominant in the follicular phase, and inhibin A is predominant during the luteal phase.

Activin is a closely related protein to inhibin, which acts in a biologically opposing manner (Fig. 102.9). Activin stimulates FSH synthesis and secretion from the pituitary gland and increases FSH binding in the ovarian follicle. In males, activin enhances spermatogenesis. Activin is produced in multiple sites, including the gonads, pituitary gland, and placenta. Follistatin, like inhibin, also inhibits FSH expression and therefore is an additional regulator of FSH biosynthesis and secretion (Fig. 102.9).

Antimüllerian Hormone. Antimüllerian hormone (AMH), a glycoprotein produced by the Sertoli cells, acts ipsilaterally via localized effects to cause regression of the Müllerian ducts in boys during early fetal development. AMH values rise from birth to relatively high levels during the first year of life in males. Levels remain stable in early childhood (with a modest late prepubertal peak) and then decline during puberty.[106] Newborn females have low or nondetectable serum levels of AMH, which rise only slightly thereafter and then rise to adult levels. As with inhibin B, AMH can be used as a laboratory marker of Sertoli cell presence and function in young males. AMH is a marker of ovarian reserve in adult women (see Chapter 123).

Prolactin. Prolactin is a peptide hormone released from the anterior pituitary gland that plays a critical role in stimulation of the mammary glands and lactation. The serum concentration of prolactin increases in normal female puberty but is not affected by male puberty. This sex difference is likely a consequence of the higher estradiol levels in females. It is an important component of breast development during and after puberty (see Chapter 127).

Sex Hormone-Binding Globulin. Between 97% and 99% of circulating testosterone and estradiol is reversibly bound to carrier proteins, including sex hormone-binding globulin (SHBG). These carrier proteins regulate the transport and biological activity of the sex steroids. Prepubertal levels of SHBG are approximately equal in boys and girls. At puberty, levels decline in both sexes, but the decline is greater in males,[107] likely due to suppression of SHBG by androgens in males.[108] The rise in adrenal androgen levels at adrenarche may explain the early drop in SHBG levels, which allows more circulating free hormone at a given concentration of testosterone. Estrogen has the opposing effect and leads to higher SHBG levels. DHEA and DHEAS bind primarily to albumin and only minimally to SHBG.

LABORATORY TESTING DURING PUBERTY

Standard assays for gonadotropins and gonadal steroids are calibrated to indicate if LH and FSH levels are very high (as found in postmenopausal women) and whether testosterone is very low (as in men with gonadal failure) or very high (as in a normal adult male). Specialized pediatric assays are needed to accurately determine the low values of sex steroids and gonadotropins found in children during pubertal development.[109] Testosterone in women and children should be measured by high-performance liquid chromatography (HPLC) tandem mass spectroscopy, which is typically performed by national labs due to high equipment cost. Free testosterone (freeT) (not bound to SHBG) may be measured as freeT, with the best results obtained by the dialysis method, and can also be estimated by a bioavailable testosterone assay. Both assays are useful in the evaluation of virilizing disorders in girls and women. Estradiol is best measured in the HPLC tandem mass spectroscopy system.

LH and FSH should be measured via highly sensitive immunometric assay and interpreted with pediatric standards, again typically requiring a national send-out laboratory. Standard LH and FSH assays are far too insensitive to accurately determine childhood values and provide meaningful information for the evaluation of most pubertal disorders. Impressively, these pediatric ultrasensitive gonadotropin and sex steroid assays can demonstrate increasing values before pubertal development is detected on physical examination. Samples are best obtained in the early morning due to the diurnal overnight rise in gonadotropins in early puberty.

KEY POINTS

- High-sensitivity pediatric assays for gonadal steroids and gonadotropins are critical to accurately characterize the low hormone levels found in children.

SUMMARY

Puberty consists of a series of complex hormonal processes that are tightly controlled by an interplay of intrinsic and extrinsic factors. Pubertal onset is not a *de novo* event, but is instead the continuation of a process that has origins in fetal life. Pubertal development includes physical changes in the breasts and genitalia, as well as changes in growth, body composition, sleep, and brain development. Obesity and other environmental factors appear to affect pubertal development, although the extent of these contributions requires further investigation.

INTRODUCTION

Disorders of puberty are among the most fascinating and complex areas of pediatric endocrinology. The combination of an extensive differential diagnosis, dramatic clinical manifestations, and intricate pathophysiology provides continual challenges for clinicians and scientists alike. Although many questions remain unanswered, phenomenal breakthroughs have occurred in elucidation of the molecular genetics, lifelong implications, and therapeutic outcomes of different forms of precocious and delayed puberty. Future advances will continue to enhance our understanding of the biological basis of normal and abnormal secondary sexual development.

PRECOCIOUS PUBERTY

Precocious puberty has been defined historically as the onset of any sign of puberty in girls younger than 8 years of age and in boys younger than 9 years of age. However, there has been considerable debate about whether these guidelines are appropriate for girls. This was precipitated by a large, office-based, cross-sectional study in which pubertal development was documented in a substantial proportion of normal girls who were younger than 8 years of age.[1] Subsequent analysis of the original data has demonstrated a correlation between body mass index (BMI) and the onset of puberty, suggesting that heavier girls may be entering puberty at slightly younger ages than lean peers. This was corroborated by a longitudinal study demonstrating that a higher BMI zscore in girls as young as 3 years of age, and a higher rate of change of BMI in early childhood is associated with earlier puberty.[2] Despite observations from international and US studies indicating that the average age of menarche has been stable over several decades, a rapid rise in the incidence of obesity in children may well lead to a secular trend in the onset of puberty in girls.[3] To what degree historical cutoffs should be revised in boys has also been challenged by a report of earlier testicular enlargement in one study, although age at attainment of Tanner V development was indistinguishable from standard norms.[4] In contrast, racial differences in the timing of pubertal development are well documented, with African American children typically starting puberty 6 to 12 months earlier than White children and Hispanic children having an onset of puberty intermediate between these racial groups.[5] Regardless of the ultimate consensus in terms of what should be considered "normal," individual factors such as growth parameters, BMI, skeletal maturation, height prediction, family history, and psychosocial status need to be taken into consideration when one is evaluating a child who presents with early puberty. It is also important to recognize that the tempo of puberty varies among children, with duration of normal puberty often being inversely proportional to age of pubertal onset.[6]

VARIANTS OF PRECOCIOUS PUBERTY

Evidence of pubertal development at a younger than normal age does not necessarily imply a pathologic condition that requires intervention. Two distinct conditions commonly occur in children when there is isolated development of a secondary sexual characteristic. *Premature thelarche* refers to isolated breast enlargement in girls, whereas *premature pubarche* describes early onset of pubic hair in boys or girls. Although different in terms of origin, pathogenesis, and implications for future health, both conditions may be considered variations of normal development. Pubic hair of infancy is a rare condition that has been described in a few case series. Although little is known about its cause and long-term natural history, pubic hair of infancy is also likely a benign entity that may represent a variant of normal pubertal development.

Premature Thelarche

Clinical Features. Premature thelarche occurs most commonly in girls between infancy and 3 years of age, although it can occur any time before the normal onset of puberty. The typical history is that breast tissue has been noted since birth or that gradual enlargement of the breasts occurs over several months without any other evidence of puberty. Growth velocity and skeletal maturation are within the normal range for age.[7] On physical examination, breast tissue usually is easily discernible, with a texture characterized by firm elasticity and a palpable margin at the periphery. Breast enlargement may be unilateral or bilateral and usually does not exceed a Tanner stage III level of development (Fig. 103.1). The nipples typically remain immature, and the vaginal mucosa usually appears unestrogenized, although estrogenization does not exclude a diagnosis of premature thelarche. When an ultrasensitive assay is used, estradiol levels have been found to be higher in girls with premature thelarche compared with controls.[8] Despite this, ovarian and uterine volumes remain in a prepubertal range, in contrast to enlargement of these structures, which is characteristic of central precocious puberty.[9]

Pathophysiology. The precise cause of premature thelarche remains unknown, although several theories about its pathogenesis have been proposed. These include individual differences in peripheral sensitivity to estradiol, as well as an alteration in the ratio of estrogen to androgens from increased sex hormone-binding globulin levels. Gain-of-function mutations in the follicle-stimulating hormone (FSH) receptor or $G_s\alpha$ have been hypothesized to be a cause of premature thelarche, although a search for molecular genetic abnormalities in these patients has been negative thus far.[10] Most cases of premature thelarche are characterized by an FSH-predominant response to gonadotropin-releasing hormone (GnRH) stimulation testing. However, it is still unclear whether this indicates involvement of the hypothalamic-pituitary-gonadal (HPG) axis in causing this condition, because this response is also characteristic of the prepubertal state in young girls.[11] One likely hypothesis is that premature thelarche exists along a continuum of hypothalamic-pituitary-ovarian activity, representing one end of a clinical spectrum that, in some patients, manifests as full-blown central precocious puberty characterized by a luteinizing hormone (LH)-predominant response to GnRH stimulation. What governs whether activation of this axis is mild, partial, transient, or complete remains a mystery. Higher serum levels of kisspeptin (a neuropeptide involved in central regulation of GnRH release) were noted in a study of young girls with premature thelarche, suggesting a central etiology.[12] It is interesting to note that premature thelarche is relatively common in girls, whereas prepubertal gynecomastia is uncommon in boys, and both FSH and estradiol levels are higher in girls than in boys at all ages.[13] Another theory is that premature thelarche and other forms of early puberty occur as a result of exposure to endocrine-disrupting chemicals (EDCs) such as phthalates, bisphenol A, pesticides, or phytoestrogens such as those found in soy formula.[14] Despite concerns about potential deleterious effects of EDCs on the reproductive system, results of existing studies are mixed, and no clear evidence of causality has yet emerged[15] (see Chapter 137).

Natural History. Follow-up studies of patients with premature thelarche have indicated several possible scenarios in terms of clinical course. Complete regression of breast tissue occurs in a substantial percentage of girls with premature thelarche, particularly in girls with onset before 2 years of age. In other patients, breast tissue may persist, or even enlarge, although initial studies failed to identify an increased risk for pubertal progression or additional medical problems.[16] In some series, as many as 14% of girls with classic premature thelarche progress to central precocious puberty, although baseline clinical and biochemical characteristics of these patients are indistinguishable from those whose condition remains stable.[17] It is reassuring that adult stature and the timing of central puberty appear to be normal in girls with nonprogressive premature thelarche.

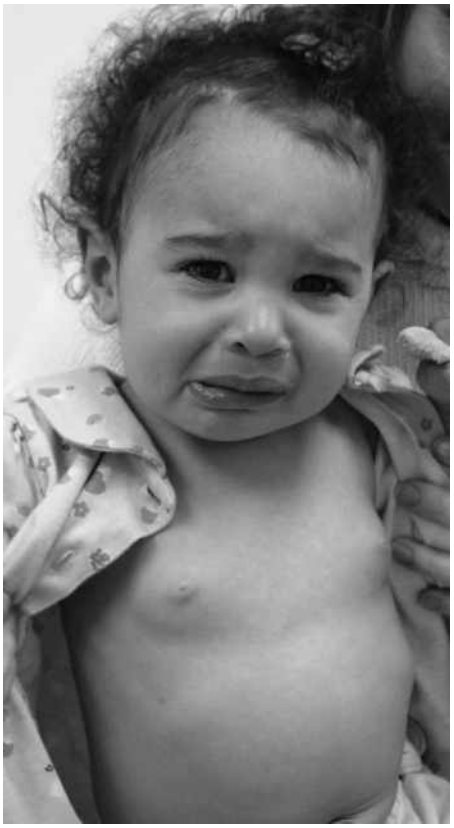

Fig. 103.1 Typical appearance of premature thelarche in a 2.5-year-old girl.

Management. In girls with typical premature thelarche, reassurance and follow-up are all that are indicated. Careful clinical assessment, including determination of growth velocity, should be performed at 3- to 6-month intervals. A bone age radiograph is helpful at the time of diagnosis and is reassuring if it is consistent with the chronologic age. Because of the possibility of progression to central precocious puberty, it is recommended that follow-up by a pediatric endocrinologist or the primary care physician continues.

Premature Pubarche

Clinical Features. Premature pubarche is characterized by the development of pubic hair in prepubertal children. Additional findings often include axillary hair, body odor, and mild acne. Most cases of premature pubarche are secondary to premature adrenarche, which is characterized by mildly elevated serum adrenal androgen levels for age, especially dehydroepiandrosterone sulfate, with values corresponding to the degree of Tanner stage development. Premature adrenarche usually occurs in children between 6 and 8 years of age but may occur earlier. Additional diagnostic criteria include the absence of other signs of puberty, such as breast development. Although growth velocity and skeletal maturation may be slightly advanced, significant virilization, such as clitoromegaly, voice change, or increased muscle mass, is

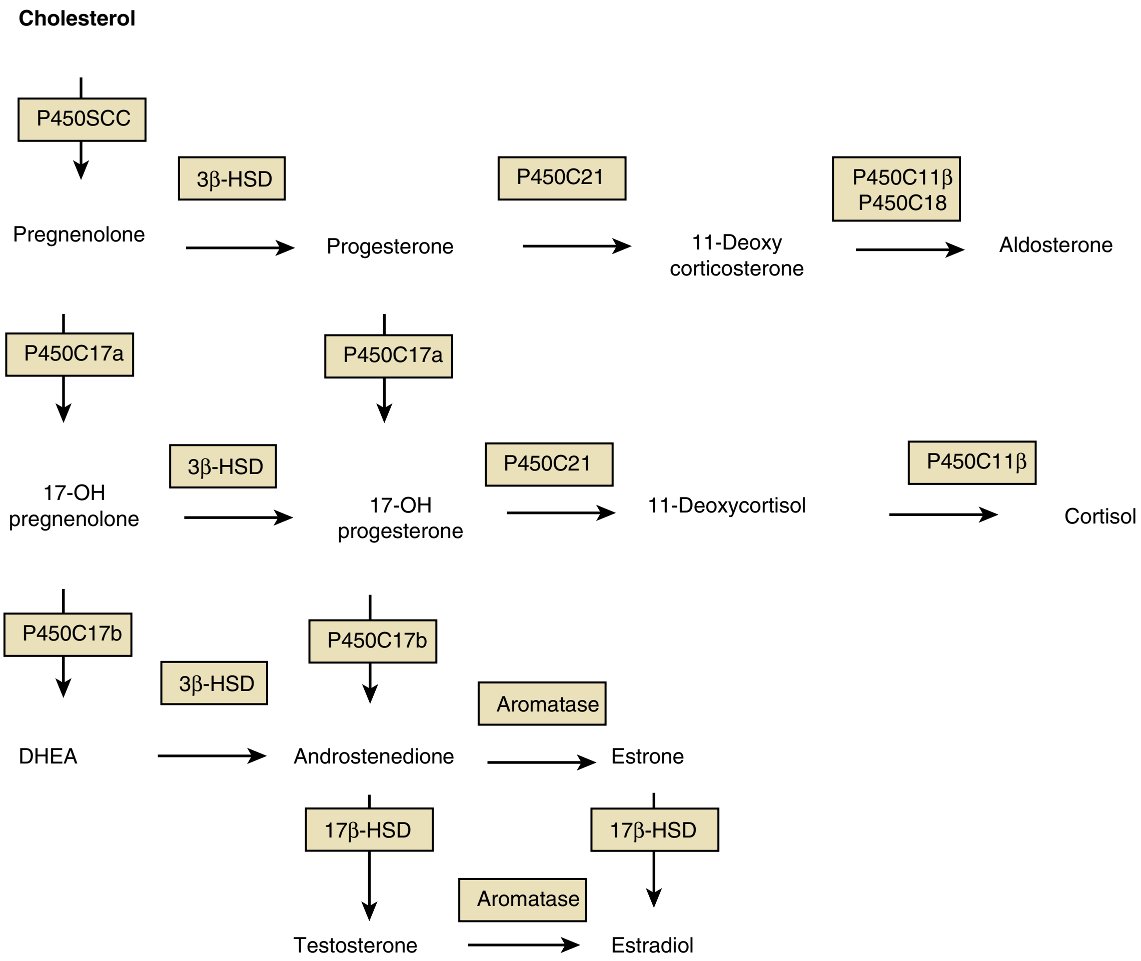

Fig. 103.2 Simplified adrenal steroidogenesis pathway. *P450SCC*, 20-22-desmolase; *P450C11β*, 11β-hydroxylase; *3β-HSD*, 3β-hydroxysteroid dehydrogenase; *P450C17a*, 17 α-hydroxylase; *P450C17b*, 17-20 desmolase; *P450C21,* 21 alpha-hydroxylase; *17β-HSD*, 17β-hydroxysteroid dehydrogenase.

absent.[18] In a study of 266 children with premature adrenarche, a significantly advanced bone age (more than 2 years) was noted in 30%. These patients were significantly taller and more overweight, and the impact of an advanced bone age on their predicted adult height (PAH) was minimal.[19] Because premature pubarche can be the presenting sign in congenital adrenal hyperplasia (CAH) or virilizing adrenal or gonadal tumors, these conditions should be considered and excluded with appropriate laboratory testing.

Pathophysiology. Attempts to define the precise clinical and biochemical profile of premature adrenarche have yielded significant heterogeneity in terms of underlying pathophysiology and concurrent metabolic features. Physiologic adrenarche, which occurs normally during midchildhood, refers to the development of the zona reticularis and an associated increase in adrenal androgen secretion. This is accompanied by alterations in adrenal enzyme activity, characterized by increases in 17,20-desmolase and 17-hydroxylase enzymes and a decrease in 3β-hydroxysteroid dehydrogenase activity[20] (Fig. 103.2). Although much progress has been made in understanding the physiology of adrenarche, the driving force behind this process in both premature and physiologic adrenarche remains unknown. Differences in peripheral metabolism of adrenal androgens have been implicated as a contributing factor in some patients, supported by the finding of elevated 3α-androstenediol glucuronide, a marker of peripheral adrenal androgen activity, in children with premature adrenarche compared with controls.[21] Partial adrenal enzyme deficiencies, including 21-hydroxylase, 3β-hydroxysteroid dehydrogenase, and 11-hydroxylase deficiencies, have been reported at variable frequencies among patients presenting with premature adrenarche,[22] whereas the prevalence of heterozygosity for 21-hydroxylase deficiency has been found to be increased in this population.[23] A search for genetic markers associated with premature adrenarche has revealed sequence variants in a number of genes encoding for steroidogenic enzymes and related receptors, although the functional consequence of these variants is unclear. Last, a subset of patients has been identified with steroid hormone profiles intermediate between those with “typical” premature adrenarche and those with CAH, a condition described as “exaggerated adrenarche.” An increased incidence of premature adrenarche has been noted in children with a history of central nervous system insult such as head trauma or hypoxic-ischemic injury, suggesting that a central process may play a role in its development.

Natural History. Despite the fact that children with premature adrenarche experience a normal onset of central puberty and achieve normal adult height, the historical assumption that this developmental variation was “benign” has proved to be incorrect. For many children, premature adrenarche may now be thought of as one stage in a continuum of metabolic abnormalities that ultimately manifests as metabolic syndrome, which is typified by insulin resistance, hyperandrogenism, and dyslipidemia. Indeed, as many as 45% of girls with premature adrenarche may develop polycystic ovarian syndrome (PCOS) later in life. Even lean girls with premature adrenarche have demonstrable alterations in body composition and insulin and androgen levels compared with controls.[24] Insulin resistance has also been reported in boys with premature adrenarche, suggesting that a propensity for future development of cardiovascular disease and type 2 diabetes pertains to both genders with this condition. Prenatal growth restriction resulting in low birth weight has been established as a common risk factor for premature adrenarche, functional ovarian hyperandrogenism, and hyperinsulinemia, implying that these metabolic derangements may be related via a shared primary abnormality. However, predictive factors in patients who will develop hyperandrogenism in later life thus far have eluded detection. Further biochemical and molecular genetic characterization of patients with premature adrenarche and its postmenarchal corollaries should yield greater understanding of pathogenesis and allow improved diagnostic discrimination and prognostic accuracy.[25]

Management. In patients with isolated pubic hair and normal linear growth, a bone age radiograph may be the only diagnostic study indicated, although the finding of normal or only mildly elevated adrenal androgens provides additional reassurance. Further investigation, including baseline or stimulated serum adrenal androgen and steroid precursor levels, is warranted if there is marked growth acceleration, advanced skeletal maturation, clitoromegaly, or other significant virilization on physical examination. Because the condition is progressive, most patients experience a gradual increase in body hair over time, accompanied by a normal rate of skeletal advancement. Insulin sensitization with metformin early after menarche in girls with premature adrenarche appears to prevent the progression of PCOS in the experimental setting. Metformin has also been shown to improve adipose body composition and may delay or prevent hirsutism, androgen excess, oligomenorrhea, and PCOS in prepubertal girls with premature pubarche and history of low birth weight.[26] However, to date, there is no evidence that pharmacologic intervention in premature adrenarche in the clinical setting is indicated, especially because we are not yet able to predict which children will develop more serious adverse associations.

Pubic Hair of Infancy. Pubic hair of infancy is a unique entity that has been described in both boys and girls. Typically, infants have isolated pubic hair growth, usually in an atypical location such as the scrotum in males and the mons in females. Linear growth, skeletal maturation, and laboratory evaluation are otherwise normal. Pubic hair tends to resolve spontaneously before 1 year of age. Given that long-term follow-up of these patients is not available, it is unclear whether there are any clinical consequences for children with this developmental variant.[27]

KEY POINTS

- Premature thelarche is a benign variant of premature pubertal development characterized by isolated breast development in girls younger than 3 years of age. The breast development is typically nonprogressive, and linear growth and age at central puberty are normal. Clinical observation is indicated because of the possibility of progression to central precocious puberty in a small subset of girls.
- Premature pubarche is characterized by premature development of pubic hair with or without axillary hair, body odor, or mild acne in prepubertal children, and mildly elevated serum adrenal androgen levels for age, especially dehydroepiandrosterone sulfate. The bone age may be mildly advanced, but growth potential is typically normal. Girls with premature adrenarche are at risk to develop polycystic ovarian syndrome later in life.

PATHOLOGIC PRECOCIOUS PUBERTY

Central Precocious Puberty

Also termed *gonadotropin-dependent,* central precocious puberty (CPP) refers to early activation of the HPG, and thus "central," axis. The underlying physiology of this form of precocious puberty therefore is identical to that of normal puberty, with the distinction being that it occurs at an abnormal time and may be the result of a pathologic condition.

Clinical Features. Girls with CPP typically present with breast enlargement and other estrogenic changes accompanied by growth acceleration and skeletal maturation. Unlike puberty that begins at a normal age, in CPP, dissociation is often noted between gonadarche and adrenarche, which may be a result of lower adrenal androgen levels during early childhood. Testicular enlargement, which is the first sign of CPP in boys, often goes unrecognized, with subsequent genital and body hair development prompting medical evaluation.

Pathophysiology. Causes of CPP can be divided into two general categories. Idiopathic CPP is used to designate cases in which no anatomic abnormality is identified, whereas in the remaining cases a central nervous system insult, either congenital or acquired, is believed to be the trigger. CPP is far more common in girls than in boys, with as many as 90% of cases having historically been designated as idiopathic.[28] However, the recognition of four monogenetic causes of CPP has resulted in a decrease in the percentage of cases deemed idiopathic.[29] The first genetic etiology discovered as the basis for CPP was a gain-of-function mutation in the KISS1 receptor (KISS1R) that has thus far been described in a single patient.[30] Subsequently, an activating mutation of the *KISS-1* gene was described in one child with very early-onset CPP.[31] In both instances, a resistance to degradation of the mutated protein compared to the wild-type protein is postulated to be the basis for the physiologic effect. Inactivating mutations in *MKRN3,* the gene encoding makorin RING-finger protein 3 that is a paternally expressed imprinted gene located in the Prader–Willi syndrome region on chromosome 15 and is involved in inhibiting puberty, were initially identified in five individuals from 15 families with familial CPP.[32] *MKRN3* mutations are well established as the most common genetic cause of CPP and have been described in sporadic as well as familial cases, where they account for up to approximately 40% of affected individuals.[33] There is evidence that *MKRN3* mutations may be underreported in boys, who experience the onset of puberty at an age very close to the lower limit of normal compared with the general population. In keeping with evidence suggesting an inhibitory role of *MKRN3* on the HPG axis is the observation that serum levels decrease in healthy children as pubertal onset draws near.[34] Mutations in Delta-like homolog 1 (*DLK1*), another paternally expressed imprinted gene, have been implicated in the pathogenesis of CPP. *DLK1* is expressed in the hypothalamus and kisspeptin-secreting neurons. In a study of a family with multigenerational CPP, a complex genetic defect in *DLK1* was identified.[35] The exact role of *DLK1* in the modulation of pubertal timing is unclear. However, it is known to be a molecular gatekeeper of adipogenesis, and adult women with *DLK1* mutations exhibit a metabolic phenotype marked by insulin resistance, obesity, and dyslipidemia. Thus, *DLK1* appears to be a unique link between metabolism and reproduction.[36] Several forms of intracranial lesions have been implicated as causative of CPP and are seen more frequently in boys. The most common is a hypothalamic hamartoma, a heterotopic mass located typically in the region of the tuber cinereum[37](Fig. 103.3). This congenital malformation consists of GnRH-secreting neurons or transforming growth factor α–producing astroglial cells, both of which

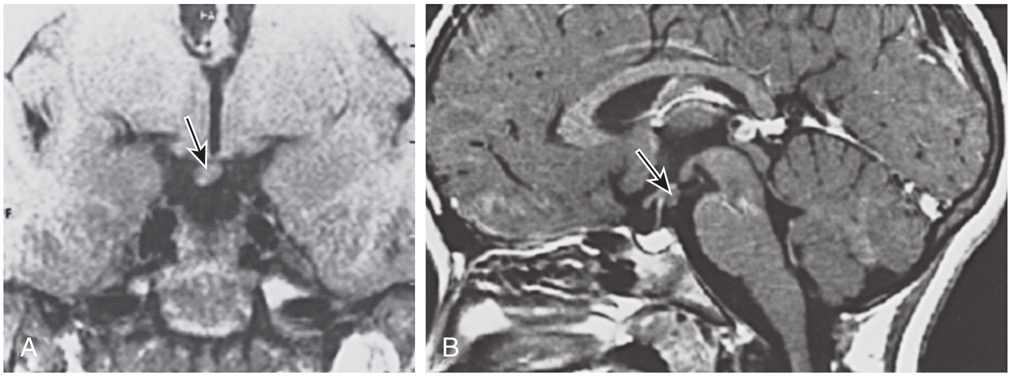

Fig. 103.3 Head magnetic resonance imaging scan revealed a pedunculated hypothalamic hamartoma in the region of the tuber cinereum, as indicated by the *arrows* in frontal (A) and sagittal (B) sections.

are believed to function as ectopic triggers on the hypothalamic pulse generator, resulting in an escape from the normal central nervous system inhibitory constraint on pubertal onset. Rarely, hypothalamic hamartomas are associated with an increased incidence of seizures, particularly gelastic, or laughing, seizures.[38] Other central nervous system abnormalities that are associated with CPP include hypothalamic-pituitary or optic chiasm tumors, pineal or suprasellar cysts, septooptic dysplasia, neurofibromatosis, head trauma, and hydrocephalus. The mechanism of intracranial abnormalities leading to precocious puberty is believed to be disruption of the neural pathways that normally exert tonic inhibition on the brain in terms of activation of puberty. This process results in a seemingly paradoxical situation in which many disorders associated with deficiencies of anterior pituitary hormones may be associated with early gonadotropin secretion.

Diagnosis. The diagnosis of CPP is based on the ability to detect activation of the HPG axis, during which sensitivity to stimulation is increased at each level of the axis. The GnRH stimulation test takes advantage of the fact that a "primed" pituitary gland responds to GnRH with a brisk elevation of gonadotropins, which in turn stimulates gonadal sex steroid secretion. Historically, synthetic GnRH (Factrel) was used for the evaluation of CPP. However, this agent is not available in the United States. Although several different protocols have been developed, the most widely used is the GnRH analog stimulation test with multiple blood sampling, in which nafarelin or leuprolide is used.

A pubertal response to GnRH stimulation is characterized by a pattern of LH predominance indicating an elevation of LH above that of FSH, whereas a prepubertal response is marked by a minimal increase in LH, if any, but may elicit an FSH response above baseline. An intermediate response, typified by an FSH-predominant response, is seen in early central puberty and in premature thelarche. A caveat of the various available tests is their inability to differentiate early central puberty from normal. This stems in part from wide variability, poor reproducibility, and lack of age-based references for the various available gonadotropin assays. However, a random ultrasensitive LH performed via immunochemiluminometric or electrochemiluminescence assay has a high sensitivity for the presence of CPP and is sufficient to confirm the diagnosis without stimulation testing. Additional evaluation of patients with CPP typically includes a magnetic resonance imaging (MRI) scan of the brain to rule out an intracranial lesion, although whether this is necessary in all patients is controversial, and a genetic diagnosis would certainly obviate this test.[39] A bone age radiograph provides important information about the degree of skeletal maturation and remaining growth potential. Pelvic ultrasonography is useful in documenting uterine and ovarian enlargement, ovarian symmetry, or the presence of cysts or other ovarian abnormalities. In patients with a prepubertal or suppressed response to GnRH stimulation, further investigation for causes of peripheral precocious puberty is indicated.

Treatment. Potential negative consequences of precocious puberty include compromise of adult stature because of premature fusion of epiphyseal growth plates and psychosocial issues related to a discrepancy between physical and emotional maturity. Therefore, the primary goal of therapy is to temporarily suppress the HPG axis to allow improved adult height and to simultaneously restore the child to a physiologic state comparable with that of his or her peers. The discovery of safe and effective treatment in the form of GnRH analogs revolutionized the therapy of CPP in the mid-1980s, and this is the treatment of choice for this condition.[40] Although the mechanism of action of GnRH analog therapy is not completely understood, it is believed that downregulation of pituitary gonadotropin-releasing hormone receptor occurs as a result of sustained high levels of GnRH. Several long-acting GnRH analogs have been used in the treatment of CPP, with subcutaneous (SC), intranasal, and intramuscular (IM) routes of administration.[41] Long-acting injectable options for GnRH analog therapy include 3-monthly and 6-monthly IM formulations, as well as a 6-monthly SC injection (Fensolvi).[42] A SC implant containing the potent GnRH analog histrelin is also available and, while marketed for annual use, lasts for at least 2 years.[43] The degree of biochemical suppression of the HPG axis varies by treatment modality, with the lower doses of extended-release injectable preparations generally being less potent than the higher doses and the histrelin implant.[44] Whether these discrepancies will translate into differences in treatment outcomes is unknown. Although untested, it is possible that GnRH antagonists may eventually have a role in the treatment of CPP as well.[45] Therapy for CPP is characterized by a return of gonadal steroids to prepubertal levels, along with a halt in pubertal progression and a deceleration in growth velocity and rate of skeletal maturation. Although ultrasensitive LH values do not predictably revert to a prepubertal range,[46] therapeutic efficacy may be documented by gonadotropin suppression in response to GnRH analog stimulation testing. Pelvic ultrasonography represents a potentially useful adjunctive tool for monitoring the effects of treatment in girls, which are characterized by regression of the internal genitalia from a pubertal to a prepubertal size. In boys, a decrease in testicular volume provides similar information. Although therapy has a profound impact on the outcome of many patients, a subset of patients with precocious puberty has been identified in whom height prognosis is quite favorable, even without treatment. These patients are characterized as having an indolent form of precocious puberty, in which pubertal progression occurs gradually, and bone age advancement is minimal.[47] Distinguishing features at presentation among this subset of patients include an increased height age/bone age ratio and PAH similar to target height when compared with patients who have rapidly progressive CPP. Although psychosocial concerns are often touted as a rationale for treatment, many studies have failed to document psychological distress in girls with early puberty, and no consensus on this aspect of treatment currently exists.[48]

Therapeutic Outcomes. Several different outcome measures have been examined with regards to the safety and efficacy of GnRH analog therapy for CPP, including adult height, bone mineralization, and resumption of puberty after treatment.[49] Each of these is discussed individually.

Adult Height. Evidence suggests that girls with onset of CPP before 6 years of age have the best response to therapy, with a height gain of 2.9 to 12.5 cm with GnRH analogs. In contrast, GnRH analogs appear to be ineffective in increasing height in children treated after age 7.5 to 8 years.[50] Indications for GnRH analog therapy other than CPP are not supported by current data.

Bone Mineralization. The effects of sex steroids on bone density are well described, with peak acquisition of bone mass occurring during puberty. Reports of a rapid decrease in bone mineralization after GnRH analog therapy in adults initially led to concerns about potential similar negative consequences in children with precocious puberty. However, several follow-up studies have now demonstrated normal bone mineral density in adult patients previously treated with a GnRH analog.[51]

Once pubertal suppression is removed via discontinuation of GnRH analog therapy, spontaneous resumption of puberty occurs. Studies have indicated a resumption of pubertal LH pulsatile secretion in most patients within 4 months after therapy, as well as normal menarche, which on average occurs 18 months after treatment is stopped. However, an inverse relationship between age at discontinuation of treatment and time to menarche has been reported.[52] Reproductive function in women treated with a GnRH analog for CPP appears to be equal to that seen in controls.[53] However, an increased incidence of hyperandrogenism has been reported independent of treatment status.

KEY POINTS

- Central precocious puberty (CPP) results from early activation of the hypothalamic-pituitary-gonadal axis, characterized clinically by early breast development in girls or testicular enlargement in boys, accelerated linear growth, and skeletal maturation, with the possibility of compromised adult height.
- CPP is commonly idiopathic, and more so in girls. The recognition of four monogenetic causes of CPP (the *MKRN3*, *KISS1*, *KISS1R*, and *DLK1* genes) has resulted in a decrease in the percentage of cases deemed idiopathic.
- The diagnosis of CPP is based on the demonstration of a luteinizing hormone (LH)-predominant response on a gonadotropin-releasing hormone (GnRH) analog stimulation test or an elevated random ultrasensitive LH performed via immunochemiluminometric or electrochemiluminescence assay.
- Treatment of CPP is with a GnRH analog. Several long-acting GnRH analogs with different routes of administration are available. The primary goal of treatment is height preservation.
- GnRH analogs improve adult height in girls with CPP, with the best response observed in those with onset of puberty before age 6 years and no apparent effect on height seen in those treated after age 7.5 to 8 years.

Peripheral Precocious Puberty

Also termed *gonadotropin-independent,* peripheral precocious puberty (PPP) refers to cases in which sex steroid exposure leads to pubertal development through a source other than activation of the HPG axis. This broad category encompasses an extremely heterogeneous group of abnormalities.[54] Evaluation and differential diagnosis depend on whether the child is a girl or boy, and on whether the clinical presentation reveals changes associated with estrogens, androgens, or both. Individual causes of PPP are discussed here, and the genotype-phenotype relationships seen in these disorders are outlined in Table 103.1.

Abnormalities of Enzymes Involved in Steroid Biosynthesis

Congenital Adrenal Hyperplasia. CAH represents a group of diseases stemming from an autosomal recessive inherited deficiency of an enzyme required for adrenal steroidogenesis (see Chapter 94) (see Fig. 103.2). The resulting disorders represent a wide spectrum of molecular genetic abnormalities and phenotypic characteristics. Excess adrenal androgen secretion as a consequence of CAH is the most common cause of abnormal postnatal virilization in children. The hallmark of these disorders is an enzymatic block in the cortisol biosynthetic pathway leading to lack of negative feedback stimulation at the level of the pituitary gland. The resulting increase in pituitary adrenocorticotropic hormone and buildup of steroid precursors proximal to the enzyme block result in an "overflow" of these precursors to the androgen synthetic pathway with subsequent overproduction of adrenal androgens. Once the diagnosis has been made, glucocorticoid replacement is indicated to result in cessation of adrenal hyperstimulation and a return of adrenal androgens to near-normal levels. The three types of CAH that may result in abnormal adrenal androgen production and subsequent virilization in prepubertal children are 21-hydroxylase, 3β-hydroxysteroid dehydrogenase, and 11-hydroxylase deficiencies.[55] Typical physical findings in girls may include pubic and axillary hair, body odor, growth acceleration, advanced bone age, and clitoromegaly. However, not all these features may be present at diagnosis. Boys present with similar changes, including increased phallic size and increased muscle mass. Testicular volume, however, is in the prepubertal range, in contrast to that observed in CPP. Rare cases of CAH with adrenal rest tissue represent an exception, in which unilateral or even bilateral enlargement of the testes may be found.[56]

Aromatase Excess Syndrome. Aromatase is the enzyme responsible for the conversion of androgens to estrogen in many tissues, including the gonads and adipocytes. Increased aromatization has been reported to be a cause of familial and prepubertal gynecomastia. Kindreds have been described in whom the aromatase excess syndrome appears to be inherited in an autosomal dominant fashion, resulting in gynecomastia in boys and precocious puberty in girls, accompanied by elevations of estradiol and estrone. Aberrant expression of the *P450* aromatase gene is thought to form the basis of the condition in at least one case, whereas an activating mutation in the aromatase gene has also been reported as a cause of familial aromatase excess.[57]

Abnormalities of G Proteins

McCune–Albright Syndrome. McCune–Albright syndrome (MAS), first described in 1937 by Albright and colleagues,[58] is a rare disorder characterized by the clinical triad of precocious puberty, polyostotic fibrous dysplasia of bone, and café-au-lait spots (see Chapter 68). Molecular genetic investigation led to the discovery that MAS is caused by an activating mutation in $G_s\alpha$, the stimulatory subunit of the G protein involved in intracellular signaling[59] encoded for by the *GNAS1* gene. This somatic mutation, which usually involves substitution of arginine for histidine or cysteine at the 201 position, is believed to occur in early embryogenesis, leading to a mosaic distribution of affected tissues. The result is a phenomenon of unregulated intracellular

TABLE 103.1 Genotype-Phenotype Relationships in Peripheral Precocious Puberty

Disorder	Affected Product	Molecular Genetic Abnormality	Functional Consequence	Inheritance	Clinical Presentation
Congenital adrenal hyperplasia	21-hydroxylase, 11-hydroxylase, 3β-hydroxysteroid dehydrogenase	*CYP21, CYP11B1, HSD3B2*	Impaired cortisol biosynthesis Excess androgen production	Autosomal recessive	Classic form: Ambiguous genitalia in newborn girls Adrenal insufficiency in boys and girls Nonclassic form: Premature pubarche in boys and girls
McCune–Albright syndrome	$G_s\alpha$	Missense mutation in *GNAS1* gene resulting in ARG201 → CYS or HIS	Mosaic distribution of constitutive activation of the *GNAS1* gene including the gonads	Sporadic	Girls: recurrent episodes of vaginal bleeding, premature breast development Boys: precocious puberty Café-au-lait macules, fibrous dysplasia of bone, other hyperfunctioning endocrinopathies
Tissue-specific $G_s\alpha$ mutation	$G_s\alpha$	Point mutation in the *GNAS1* gene resulting in ALA366→ SER	Constitutive activation in testes, inactivation in other tissues	Sporadic	Boys: precocious puberty, pseudohypoparathyroidism
Familial male precocious puberty	Luteinizing hormone receptor	Single amino acid substitution in the LH receptor	Constitutive activation of the LH receptor in Leydig cells	Autosomal dominant, sporadic	Precocious puberty in males
Aromatase excess syndrome	Aromatase enzyme	Polymorphism of *P450* aromatase gene; inversions of chromosome 15q21.2-3	Aberrant transcription of aromatase gene; gain-of-function mutation of aromatase gene	Autosomal dominant, X-linked	Girls: precocious puberty Boys: gynecomastia
FSH-activating mutation	FSH receptor	Single amino acid substitutions in the FSH receptor	Constitutive activation of the FSH receptor. Increased affinity of FSH receptor for human chorionic gonadotropin	Autosomal dominant	Females: familial gestational ovarian hyperstimulation syndrome, ovarian cysts*, premature thelarche* Males: preservation of spermatogenesis after hypophysectomy in one male

FSH, Follicle-stimulating hormone; *LH*, luteinizing hormone.
*, (theoretical)

accumulation of cyclic adenosine monophosphate, which in turn stimulates downstream gene transcription. Hyperfunction of endocrine glands is a cardinal feature of MAS, with numerous organs potentially affected, including the adrenal glands, parathyroid glands, pituitary gland, thyroid gland, and gonads.[60] Rare involvement of nonendocrine tissues has also been reported in MAS and has included hepatobiliary disease, cardiac disease, and sudden death.[61] Unregulated sex steroid secretion from the gonads in prepubertal children forms the basis of precocious puberty in MAS, which, although it occurs in both sexes, is more commonly reported in females. In prepubertal girls, precocious puberty is characterized by sporadic ovarian cysts with subsequent elevations in serum estradiol levels. Spontaneous regression of the cysts can lead to withdrawal bleeding, whereas long-term unopposed estrogen secretion can result in uterine breakthrough bleeding.

The clinical presentation of MAS is extremely variable, ranging from patients with extensive skin (Fig. 103.4) and bone (Fig. 103.5) involvement and progressive precocious puberty to patients with only mild manifestations. Patients exhibiting a forme fruste of MAS are also recognized, in whom isolated involvement of bone, adrenal glands, or gonads may occur. Adolescent girls with MAS tend to have a lower ovulatory rate compared with controls (36% vs. 52%).[62] The variable clinical presentation reflects, in part, the fact that the $G_s\alpha$ mutations that cause MAS are postzygotic and mosaic. Macroorchidism is commonly seen in boys with MAS, and Sertoli cell-only *GNAS1* mutations have been reported as a cause.[63] Thus, different individuals and different organs within the same individual may contain variable proportions of cells that harbor the $G_s\alpha$ mutation. Tissue-specific imprinting of the *GNAS1* gene may contribute to the observed phenotypic heterogeneity.[64] In patients with rapidly progressive precocious puberty, historical treatment has involved medroxyprogesterone or an aromatase inhibitor, such as testolactone. Unfortunately, these therapies have been largely disappointing. Although the newer-generation aromatase inhibitor anastrozole was not shown to be beneficial in a study of 27 girls with MAS,[65] therapy with letrozole appears to be more promising. In a pilot study of nine girls with MAS, a significant decrease in frequency of menstrual bleeding and rate of growth was observed.[66] Long-term outcomes of 28 girls, including the nine girls from the initial pilot study, treated with letrozole for up to 10 years showed a significant improvement in PAH, and no adverse events.[67] Another option is tamoxifen, a selective estrogen receptor modulator, which was shown to be safe and efficacious in 25 girls with MAS and precocious puberty.[68] A retrospective study of eight girls treated with tamoxifen for 3 to 8 years and followed for a mean period of 8.3 years showed cessation of vaginal bleeding and increased PAH, with no noted alteration in uterine volumes or endometrial thickness.[69] However, long-term data are lacking.

A 1-year treatment with Fulvestrant, a pure estrogen receptor antagonist, in 30 girls with PPP related to MAS resulted in a decrease in vaginal bleeding (from 12 days to 1 day per year) and a significant decrease in the rate of skeletal maturation.[70]

Regardless of the pharmacologic agent used, the underlying disease process is unchanged. Once the onset of central puberty commences, the HPG axis may override the independent gonadal function, although persistent autonomous ovarian activity has been documented in postmenarchal girls and women with MAS and a history of precocious puberty. Long-term data suggest that these women have successful spontaneous pregnancies, despite a longer than average time to conception.[71]

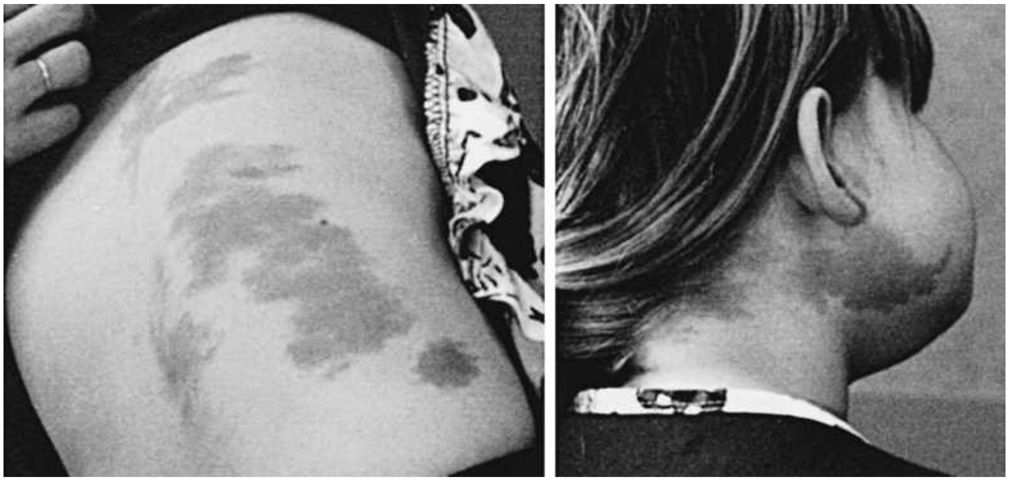

Fig. 103.4 Café-au-lait skin pigmentation in a 4-year-old girl with McCune–Albright syndrome who presented with precocious puberty. The irregular borders of these lesions designate them as "coast of Maine" café-au-lait spots, as opposed to the smooth-bordered "coast of California" variety characteristic of neurofibromatosis. The propensity of these lesions to stop abruptly at the midline is demonstrated.

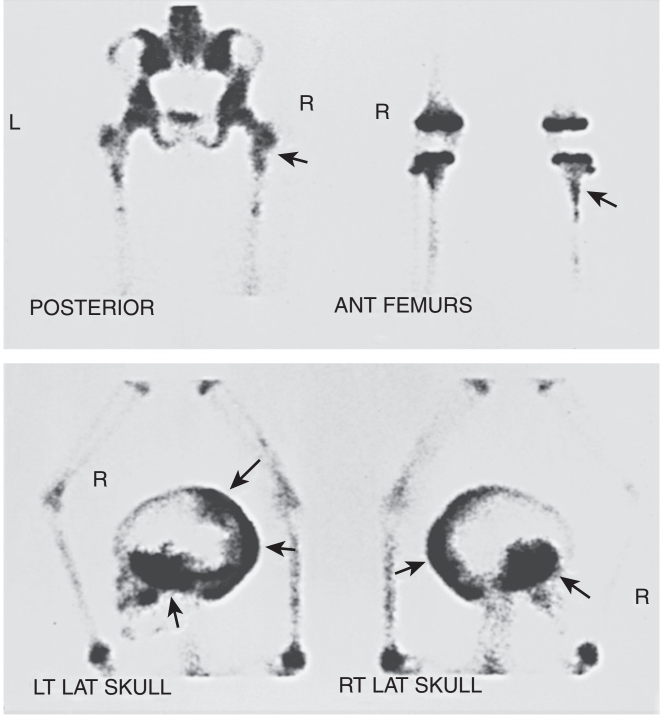

Fig. 103.5 Bone scan of a patient with polyostotic fibrous dysplasia. The *arrows* indicate areas of increased uptake.

Less data are available on the treatment of boys with MAS and PPP, given the rarity of this condition. Similar to the treatment approach in other forms of PPP in boys, the combination of anastrozole and the competitive androgen blocker bicalutamide has been reported and appears to be a promising treatment option.[72]

A rare and fascinating mutation of $G_s\alpha$ has been described in two unrelated males, in which a mutant G protein subunit exhibits temperature dependence resulting in both activating and inactivating properties, depending on the tissue involved. In the testes, which are cooler than the core body temperature, the abnormal $G_s\alpha$ is activated, leading to autonomous sex steroid production and testotoxicosis. In contrast, in skin fibroblasts, which are at 37°C, thermal instability of the abnormal protein is observed, leading to rapid degradation of $G_s\alpha$, along with a subsequent decrease in $G_s\alpha$ activity and pseudohypoparathyroidism.[73]

Abnormalities of Gonadotropin Receptors

Familial Male Precocious Puberty. Familial male precocious puberty (FMPP), also termed *testotoxicosis,* is a form of PPP that occurs only in males. In this disorder, the LH receptor exhibits constitutive activation, leading to autonomous sex steroid secretion and early pubertal development. The underlying abnormality is a heterozygous mutation in the gene that encodes the LH receptor, which results in transcription of an abnormal receptor product with aberrant function. The first described mutation, found in eight affected individuals in different families, involved the substitution of glycine for aspartate at position 578 in the sixth transmembrane helix of the LH receptor. Since then, additional mutations involving the first, second, and third transmembrane domains and the third intracellular loop of the LH receptor have been described.[74] Although the typical inheritance pattern for FMPP is autosomal dominant, patients with sporadic mutations have also been identified. Females with activating mutations of the LH receptor have no phenotypic abnormalities, likely because the actions of both LH and FSH receptors are required for ovarian steroidogenesis.[75]

Patients with FMPP present in early childhood (typically by 4 years of age) with growth acceleration and progressive virilization, including growth of pubic hair and phallic enlargement. The testes are usually small in comparison with the degree of virilization and may be nodular, with histology demonstrating Leydig cell hyperplasia. Serum testosterone levels are in the adult male range, whereas serum gonadotropins are suppressed, as is the response to GnRH stimulation testing. Untreated males with FMPP experience continued skeletal maturation with early epiphyseal closure and final short stature. Fertility is generally normal, although oligospermia and morphologic testicular abnormalities have been described in some affected individuals.[76] Pharmacologic regimens shown to be effective in the treatment of FMPP have included the antisteroidogenic agent ketoconazole, although there are concerns regarding potential liver toxicity. Although effective, combination therapy with spironolactone and the aromatase inhibitor testolactone has been replaced with the combination of the selective androgen receptor blocker bicalutamide and a third-generation aromatase inhibitor because of the need for less-frequent dosing and more selective androgen action blockade. The efficacy of this approach has been reported in several small studies.[77] In one prospective trial involving 14 boys, a decrease in the rate of growth and skeletal maturation was noted after 1 year of treatment with bicalutamide and anastrozole. Gynecomastia and breast tenderness were the most common treatment-related adverse effects.[78] The addition of a long-acting GnRH analog once central puberty begins has provided useful adjunctive therapy and improved adult height in the setting of FMPP.[79] Interestingly, intermittent spontaneous resolution has been reported in a patient with genetically confirmed FMPP.[80]

Ovarian Cysts. Use of high-resolution ultrasonography has revealed that ovarian cysts are common in prepubertal girls of all ages. Although these cysts are typically asymptomatic, they may become transiently functional, causing acute onset of breast development because of elevated ovarian estradiol secretion. Spontaneous resolution of these cysts is followed by a decrease in breast tissue, leading to a history of waxing and waning breast development. The underlying pathophysiology of this cause of precocious puberty is poorly understood and may represent transient activity of the HPG axis, a $G_s\alpha$ mutation (forme fruste of MAS), or an unidentified FSH receptor mutation. Although activating mutations of the FSH receptor have been linked to gestational ovarian hyperstimulation syndrome,[81] no case of precocious puberty resulting from such a mutation has been described thus far.

TUMORS

Sex steroid production by neoplastic tissue in prepubertal children is a rare but important cause of PPP. Presenting symptoms depend on the location and type of tumor and whether androgens, estrogens, or both are being produced.

Gonadal Tumors

Ovarian Tumors. Primary ovarian neoplasms in children may originate from sex cord or stromal tissue, epithelium, or the germ cell line, with granulosa cell tumors being the most frequent ovarian tumor that induces precocious puberty. Although the average age of prepubertal children presenting with ovarian tumors is 10 years, precocious puberty caused by ovarian neoplasms has been reported in infants. Most ovarian tumors produce estrogen, resulting in feminization, although androgen production may also occur, leading to hirsutism and other signs of virilization. Additional clinical findings often include abdominal symptoms such as pain, distention, ascites, or a palpable mass. The frequency of precocious puberty as a feature of ovarian tumors varies, depending on the type of tissue involved, but may be as high as 71%. Primary treatment is surgical with or without adjuvant chemotherapy, and the prognosis is generally good, particularly in patients with the juvenile granulosa cell tumor variety.[82]

Testicular Tumors. Leydig cell tumors, which make up approximately 3% of all testicular neoplasms, are the most common gonadal stromal tumors associated with precocious puberty in boys. Although 10% of such tumors are malignant in adults, they are usually benign in children. Precocious puberty caused by testicular tumors is typically characterized by elevated serum testosterone levels and evidence of virilization. However, sex cord (Sertoli cell) tumors have rarely been described in which gynecomastia, as well as virilization, is a feature of the clinical presentation. In several cases, somatic activating mutations of the LH receptor have been shown to form the basis for Leydig cell tumors associated with precocious puberty.[83]

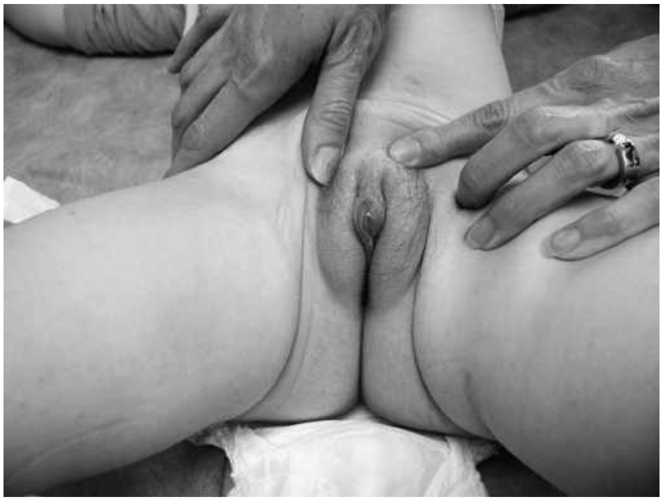

Fig. 103.6 **Virilization of the genitalia in a 2-year-old girl with an androgen-secreting adrenocortical adenoma.** (Courtesy Dr. Emily Walvoord.)

Adrenal Tumors

Adrenocortical adenomas and carcinomas are extremely rare causes of precocious puberty in childhood but have been reported to occur even during infancy. The vast majority of such tumors are virilizing (Fig. 103.6) as the result of elevations in serum adrenal androgen levels, which may or may not be accompanied by hypercortisolism. However, in rare instances, variations in biosynthetic enzyme activity within the tumor may result in increased plasma concentrations of estrogens, with subsequent feminization. Most functioning childhood adrenocortical neoplasms are malignant, and surgical resection is the treatment method of choice. Secondary activation of the HPG axis has been reported after removal of a virilizing adrenal tumor.[84]

Germ Cell Tumors

Nongonadal germ cell tumors as a cause of precocious puberty have been reported to arise in numerous locations, including the liver, lungs, mediastinum, pineal gland, basal ganglia, thalamus, and hypothalamus. Tumor markers useful in the diagnosis and follow-up of germ cell tumors include α-fetoprotein, β-human chorionic gonadotropin (β-hCG), and pregnancy-specific β_1-glycoprotein.[85] Because precocious puberty in this setting occurs as a result of ectopic β-hCG secretion, which mimics the action of LH on testicular Leydig cells, the overwhelming majority of cases are reported in boys. Increased tumor aromatase activity in the setting of simultaneous β-hCG production has been postulated to account for rare cases of precocious feminization in girls presenting with germ cell tumors.

Exogenous Sex Steroids

Exogenous sex steroids—estrogens or androgens—can lead to the development of secondary sexual characteristics in prepubertal children. Examples of widely available exogenous steroids include oral contraceptive pills and estrogen- or androgen-containing topical preparations. Systemic absorption of estrogens found in various cosmetics and hair products has also been linked to precocious puberty.[86]

HYPOTHYROIDISM

More appropriately thought of as a form of pseudoprecocious puberty (PSPP), the rare association between severe long-standing hypothyroidism and early sexual development (Van Wyk–Grumbach syndrome) was described in the 1960s.[87] Although the incidence of this condition has not been systematically evaluated, 24% of 33 children with profound hypothyroidism had evidence of PSPP.[88] Those with PSPP were older and had higher TSH levels. This condition is accompanied by the seemingly paradoxical finding of significantly delayed skeletal maturation and growth arrest. In girls, the clinical presentation consists of estrogenic manifestations, including breast development and changes in the vaginal mucosa. Galactorrhea and vaginal bleeding may be present, and in some patients are severe. Pelvic ultrasonography reveals enlarged ovaries with multiple cysts. Boys present with macroorchidism, often without evidence of virilization (Figs. 103.7 and 103.8), which is consistent with the finding of low serum testosterone levels.

Investigation of the HPG axis of boys with severe primary hypothyroidism and macroorchidism reveals a prepubertal pattern of gonadotropin response to GnRH stimulation, although baseline levels of TSH, prolactin, and pituitary gonadotropins are elevated. The original hypothesis for increased gonadotropins in addition to TSH has been supported by the finding of an elevated FSH response to TSH stimulation in a patient with hypothyroidism-induced macroorchidism,[89] whereas evidence also exists of a component of cross-reactivity of TSH at the level of the FSH receptor.[90] Both of these mechanisms would theoretically result in FSH-mediated gonadal stimulation, causing Sertoli cell proliferation with subsequent testicular enlargement in boys and ovarian hyperstimulation in girls. The lack of LH-induced testosterone secretion in hypothyroid boys with elevated gonadotropins has been attributed to an inhibitory influence of prolactin on LH action at the Leydig cell. Most of the clinical and biochemical abnormalities in these patients gradually resolve with restoration of euthyroid status, although macroorchidism may persist.[89]

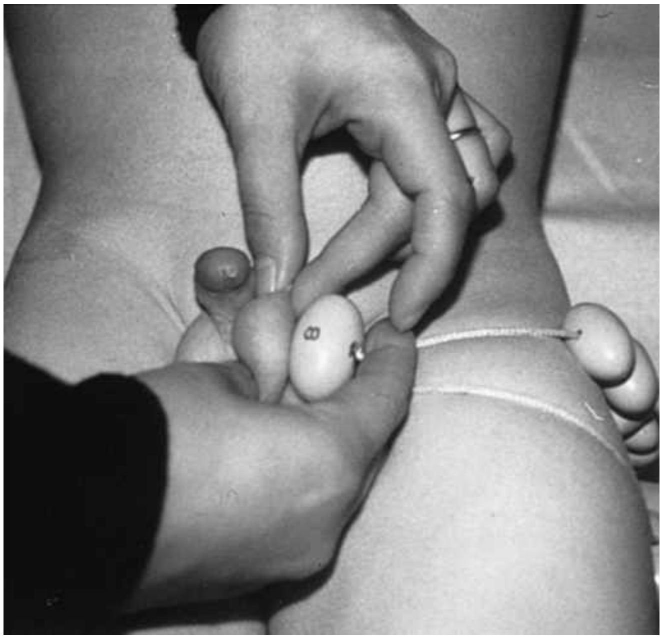

Fig. 103.7 **Macroorchidism in an 8-year-old boy with severe long-standing hypothyroidism secondary to autoimmune thyroiditis.** Testicular volume was 8 mL, in contrast to a normal prepubertal testicular volume of 1–3 mL.

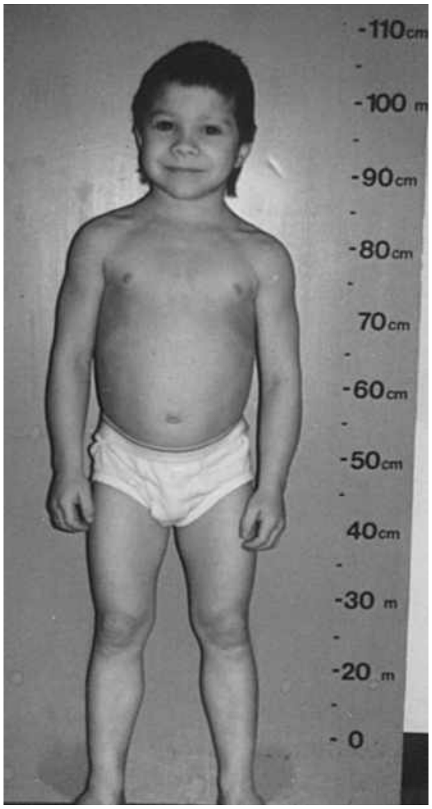

Fig. 103.8 **Additional manifestations of hypothyroidism in this child included severe growth arrest, coarse facial features, dry skin, and sallow complexion.** Bone age radiograph was significantly delayed at 5 years.

KEY POINTS

- There are many etiologies of peripheral precocious puberty (PPP), with diverse manifestations resulting from exposure to androgens, estrogens, or both, independent of activation of the hypothalamic-pituitary-gonadal axis. Most common etiologies include congenital adrenal hyperplasia (CAH), McCune–Albright syndrome (MAS), and familial male precocious puberty (FMPP).
- CAH is the most common cause of abnormal postnatal virilization in children. The excess androgen production results from enzymatic block in the cortisol biosynthetic pathway, most common being 21-hydroxylase deficiency. Glucocorticoid replacement aims to decrease shunting of the enzyme precursors to the androgen pathway.
- The early pubertal development in MAS results from spontaneous ovarian cysts caused by an activating mutation in $G_s\alpha$, a stimulatory subunit involved in intracellular signaling of multiple hormone receptors. Treatment with letrozole, a third-generation aromatase inhibitor, tamoxifen, an estrogen receptor modulator, or Fulvestrant, an estrogen receptor antagonist, appear to decrease the frequency of vaginal bleeding and improve the rate of skeletal maturation.
- FMPP is a male-limited form of PPP that results from activating mutations in the luteinizing hormone receptor leading to autonomous androgen production. Combination therapy with an androgen receptor blocker and an aromatase inhibitor decrease the rate of growth and skeletal maturation and improves growth potential.

DELAYED PUBERTY

Definition

Delayed puberty refers to the absence of pubertal onset by the expected age or, once puberty has commenced, failure of appropriate progression. Although its outward manifestations are subtle, delayed puberty is nonetheless profoundly distressing to the adolescents affected by it, who continually compare themselves to their peers and find themselves lacking. A large array of disorders may manifest as delayed puberty, necessitating a diagnostic process that incorporates patience, astute observation, and consideration of multiple potential etiologies. Discovery of the molecular genetic basis for both benign and pathologic forms of delayed puberty will continue to offer tremendous insight into the biology of human reproduction.

Girls are considered to have delayed puberty if they reach 13 years of age without evidence of pubertal changes; in boys, the analogous age is 14 years. Progression of puberty denotes the development of secondary sexual characteristics according to a predictable and sequential series of stages first described by James Tanner.[91] Whereas a postponement of pubertal onset often represents a benign variation of normal development (discussed in the following section), arrest of puberty once it has begun is almost always abnormal and indicative of an underlying pathologic condition.

BENIGN VARIANTS OF DELAYED PUBERTY

Constitutional Delay of Growth and Puberty

Constitutional delay of growth and puberty (CDGP) refers to a well-described variation of normal growth that is the most common cause of delayed puberty in both boys and girls. Children with this condition are short for their genetic background, often below the third percentile, and have delayed skeletal maturation, as well as delayed puberty. In many cases, there is a family history of "late bloomers," manifested by an older age at menarche in women or significant linear growth occurring in the late teenage years in men. The precise cause of the altered growth pattern observed in CDGP is unknown. Observations of the strong familial nature of the condition have led to investigations of potential inheritance patterns. Evidence thus far suggests the presence of a genetic predisposition with an autosomal dominant effect in addition to environmental modifiers. However, precisely which genes and/or modifiers are responsible for CDGP remains largely unknown. A search for mutations in genes known to cause isolated hypogonadotropic hypogonadism (HH) such as *KISS1R, FGFR1, GNRHR, TAC3,* and *TAC3R* in patients with CDGP, has thus far been negative. Mutations in the *IGSF10* gene have been identified in six unrelated families from a large Finnish cohort. This gene is involved in GnRH neuron migration during embryogenesis.[92] Several inactivating mutations in the growth hormone secretagogue receptor have been described, suggesting a role of ghrelin in the pathogenesis of CDGP.[93] In CDGP, boys and girls appear to be equally affected.[94]

Diagnosis. The diagnosis of CDGP rests on the typical clinical findings of short stature, delayed bone age, and low-normal growth velocity, combined with the absence of any other identifiable cause of short stature and pubertal delay. Baseline gonadotropin levels are low, and the clinical and biochemical features are virtually indistinguishable from those observed in patients with gonadotropin deficiency. This often results in a "wait and see" policy in terms of establishing which patients may ultimately experience spontaneous puberty. However, the ability to differentiate CDGP from pathologic causes is desirable because of anxiety regarding whether or not puberty will ensue. Although no single test is considered foolproof, several different strategies appear useful. One of the earliest employed involves stimulation tests using GnRH analogs such as nafarelin, leuprolide, and triptorelin. Peak LH levels following administration of a GnRH analog are reported to be significantly higher in patients with constitutional delay as compared with patients with HH.[95] High sensitivity and specificity for discrimination of CDGP from other etiologies of delayed puberty in boys has also been reported using human chorionic gonadotropin (hCG) stimulation tests.[96] Another approach relies on measurements of the free α-glycoprotein subunit after GnRH stimulation. Measurement of basal inhibin B also appears to have a good ability to differentiate between CDGP and HH. In a study of 82 boys with pubertal delay, a baseline inhibin B level of 35 pg/mL or less had a 100% sensitivity and specificity to differentiate between HH and CDGP in boys at genital stage 1.[97] The kisspeptin stimulation test shows promise in being able to distinguish youth with CDGP from those with HH, and more study is warranted.[98] Alternatively, failure of spontaneous pubertal onset by a bone age of 12 years for girls and 13 years for boys would clearly be inconsistent with a diagnosis of CDGP, and causes of pathologic hypogonadism should be sought.

Treatment. The practice of using anabolic agents in adolescents with CDGP originated from recognizing the potential adverse psychological consequences of sexual immaturity and from concerns about possible decreased bone mineral density in these patients. Short-term low-dose anabolic therapy has been shown to be both safe and effective in promoting growth and pubertal development without advancing bone age. Specific agents that have been used include fluoxymesterone, oxandrolone, and oral or transdermal testosterone. However, the mainstay of therapy employs low-dose IM testosterone, given monthly on a continuous or intermittent basis for several months and up to 1 year. Another proposed advantage of such therapy is based on the concept that exogenous androgens may advance maturation of the HPG axis, to "jump start" puberty. Despite this hypothesis, there is little evidence that treatment with exogenous testosterone affects the timing and tempo of endogenous pubertal development in boys with constitutional delay in whom considerable heterogeneity in baseline HPG activation has been well documented. Similar therapeutic regimens have been administered in girls with CDGP using conjugated or unconjugated oral estrogens or transdermal 17β-estradiol, with comparable results.[99]

Outcome

Adult Stature. Adult height in patients with CDGP has been examined in relation to predicted height and target height. The majority of studies indicate that individuals with CDGP attain an adult height that is below the target height but within the midparental range,[100] whether or not treatment with short-term anabolic agents is undertaken. Accuracy of predicted heights as determined by the Bayley–Pinneau method is variable. Although most investigators have found that height predictions are fairly reliable,[95] overestimating and underestimating adult heights have also been reported using this method. Disproportionality—when the spine is short in relation to the limbs (*eunuchoid* body habitus)—has been described in CDGP and has been attributed to decreased spinal growth during the characteristically attenuated pubertal growth spurt observed in these patients. A longer period for limb growth is also noted.

Bone Mineralization. The effects of sex steroids on the acquisition of bone mineral density are well known, and hypogonadal states are a cause of osteoporosis in adulthood.[101] Although normal bone mineral density has been reported in boys and men with a history of CDGP, a significant decrease in bone mineral density has also been identified in this population,[102] suggesting a possible negative impact of delayed sex steroid exposure on bone accretion. Treatment with exogenous testosterone during adolescence has been shown to improve bone density and bone turnover, providing additional support for the use of short-term anabolic agents in these patients. The effects of androgens on bone mineralization and epiphyseal fusion are mediated via aromatization to estrogen. This has been demonstrated by rare clinical examples of estrogen receptor mutations and aromatase deficiency in males, conditions that are characterized by profoundly decreased bone mineral density and open epiphyses, despite normal serum testosterone levels.[103,104]

PATHOLOGIC DELAYED PUBERTY

Pathologic causes of delayed puberty have conventionally been grouped into two distinct categories, depending on which portion of the HPG axis is affected. HH refers to conditions in which gonadotropins are low, implying an abnormality at the level of the hypothalamus or pituitary gland, or both, whereas *hypergonadotropic hypogonadism* refers to conditions in which LH and FSH are elevated, indicating a lack of negative feedback at the level of the pituitary gland and localizing the problem to the gonads. This delineation has become less useful with the recognition of genetic mutations involving hypothalamic-pituitary hormones and their receptors, some of which result in hypergonadotropism rather than hypogonadotropism. Therefore, causes of hypogonadism are grouped according to the location within the HPG axis of the affected hormone. The term *hypothalamic-pituitary hypogonadism* is used to designate disorders of hormones (and their receptors) originating from this portion of the axis, whereas *primary hypogonadism* encompasses disorders of the gonads themselves. In both forms of hypogonadism, the end result is a failure of normal ovarian or testicular sex steroid production. Discussed later in this chapter, exogenous sex steroid replacement is therefore the cornerstone of therapy for all types of pathologic delayed puberty, regardless of the cause.

Hypothalamic-Pituitary Hypogonadism

Hypothalamic-pituitary hypogonadism refers to conditions in which hypothalamic GnRH, pituitary gonadotropins, or both, are either deficient or inactive. This includes a diverse group of disorders with varied pathophysiology. Some causes stem from an isolated abnormality in hypothalamic GnRH, and others stem from an isolated abnormality in pituitary gonadotropins (LH and/or FSH), but conditions also exist in which both hypothalamic and pituitary dysfunction are present. Similarly, hypothalamic-pituitary hypogonadism may be the sole manifestation of the disorder, or there may be wide-ranging effects on additional body systems. Partial progression through puberty in a subset of affected individuals is a common feature of many conditions, leading to clinical heterogeneity even within the same kindred. Another shared trait among patients with hypothalamic-pituitary hypogonadism is a characteristic body habitus. An arm span of at least 5 cm more than height and an upper-to-lower segment ratio of less than 0.9 confirm the presence of eunuchoid proportionality. When left untreated, hypothalamic-pituitary hypogonadism is also associated with an increase in adult height owing to the lack of sex steroid-induced skeletal maturation and epiphyseal fusion.[105] Although the exact cause of many cases of hypothalamic-pituitary hypogonadism remains unknown, there has been significant progress in identifying the precise molecular genetic abnormalities responsible for several specific disorders.[106] Single-gene defects are estimated to account for 30% of patients with hypothalamic-pituitary hypogonadism. The list of single-gene defects associated with hypothalamic-pituitary hypogonadism continues to grow and is summarized in Table 103.2, along

TABLE 103.2 Genetic Etiologies of Hypogonadotropic Hypogonadism

Category	Affected Genes	Additional Findings
Disorders of migration of the GnRH neuron (Kallmann syndrome)	*ANOS* (*KAL-1*)	Anosmia/hyposmia, synkinesia, hearing loss, renal agenesis
	FGFR1, FGF8	Dental agenesis, digital bony abnormalities, cleft palate, agenesis of corpus callosum
	PROK2/PROKR2	Fibrous dysplasia, synkinesia, and seizures
	CHD7	Features of CHARGE syndrome
	Other identified genes: *FGF17, WDR11, SEMA3A, IGSF10, SMCHd1, CCDC141, FEZF1*	
Disorders of the GnRH pulse generator	*TAC3/TACR3*	Partial or complete reversal of HH may occur
	KISS1/KISS1R	HH can be reversible
	GNRH1	Cryptorchidism, micropenis
		Phenotype can be reversed by pulsatile GnRH administration
Disorders of pituitary gonadotropes	GnRH receptor	Partial HH
	LH β subunit	M: delayed puberty
		F: homozygous females have oligomenorrhea heterozygous females are unaffected
	FSH β subunit	M: azoospermia, low testicular volume, normal testosterone
		F: ovarian dysgenesis, premature ovarian failure
	DAX-1	Congenital adrenal hypoplasia
	SF-1	XY sex reversal
		Adrenal insufficiency
	Transcription factor defects:	
	PROP1, LHX3	Combined anterior pituitary hormone deficiencies
	HESX1	Septooptic dysplasia, variable anterior pituitary hormone deficiencies
Disorders associated with obesity	Leptin (*LEP*), leptin receptor (*LEPR*)	Hyperphagia, childhood-onset morbid obesity
		Treatment with leptin reverses HH
	Prohormone convertase (PC1)	Childhood morbid obesity, hypocortisolism, elevated proinsulin
Disorders associated with neurodegenerative disease	*POLR3A/POLR3B* (4H syndrome)	Hypodontia, hypomyelination
	RNF216, PNPLA6 (Gordon–Holmes syndrome)	Cerebellar ataxia, early dementia

CHARGE, Coloboma, heart disease, choanal atresia, retarded growth and development, and/or deafness; *F*, females; *FSH*, follicle-stimulating hormone; *GnRH*, gonadotropin-releasing hormone; *LH*, luteinizing hormone; *HH*, hypogonadotropic hypogonadism; *M*, males.

with descriptions of the associated phenotypes. Once a diagnosis of hypothalamic-pituitary hypogonadism has been made, MRI is recommended to rule out an intracranial lesion. Ultrasensitive gonadotropin assays or a GnRH analog stimulation test may be useful in confirming and determining the degree of hypogonadotropism. Hypothalamic GnRH deficiency may be differentiated from pituitary gonadotropin deficiency by administration of pulsatile GnRH, which usually results in subsequent elevations of LH and FSH in individuals with isolated hypothalamic defects. Fertility is therefore potentially possible with the use of exogenous GnRH or gonadotropin therapy, although sex steroid replacement is generally the therapy of choice for induction of puberty and maintenance of secondary sexual characteristics. Interestingly, spontaneous reversal of hypothalamic-pituitary hypogonadism has been noted after discontinuation of sex steroid replacement in approximately 10% of patients with either Kallmann syndrome (KS) or normosmic HH.[107] This suggests that genetic defects in some patients with hypothalamic-pituitary hypogonadism may prolong the time to maturation of the HPG axis. Specific causes of hypothalamic-pituitary hypogonadism are discussed in the following sections.

Kallmann Syndrome. The prototype of GnRH deficiency exists in the form of KS, which refers to the association between HH and anosmia, first described in 1944.[108] Sporadic cases and multiple heritable forms have been described, including X-linked, autosomal recessive, and autosomal dominant. The X-linked form of the disease is caused by mutations in the *KAL* gene on Xp22.3. This gene encodes for the extracellular matrix glycoprotein anosmin-1, which is a cell-adhesion molecule essential for normal neuronal migration during embryogenesis. Highly conserved across species, anosmin-1 appears to have both direct and permissive roles in olfactory bulb development, GnRH migration, and axonal growth.[109] Numerous mutations within the *KAL* gene have been described in patients with KS. Interestingly, significant clinical heterogeneity in the degree of hyposmia/anosmia and hypogonadism exists among patients bearing identical mutations, implying the presence of important modifier genes and/or environmental factors in the expression of the syndrome. The list of specific genes underlying the other forms of KS and normosmic HH is expanding.[110] Loss-of-function mutations in *FGFR1* and mutations in the prokineticin-2 signaling and in nasal embryonic LH-releasing hormone factor genes have been reported in association with the autosomal dominant form of KS. Of these, loss-of-function mutations in *FGFR1* are particularly common and have been detected in 7% of patients with normosmic HH. These mutations likely act in concert with other genetic and environmental factors to explain the variable phenotype in these patients. Autosomal recessive mutations in *TAC3,* the gene encoding neurokinin B, as well as the gene encoding the neurokinin B G protein–bound receptor, have also been commonly reported in patients with idiopathic HH. Although its mechanism of action is unclear, neurokinin B is expressed in the same neurons that express kisspeptin and is thus thought to stimulate GnRH.

Given that HH and anosmia also occur in CHARGE (coloboma, heart disease, choanal atresia, retarded growth and development, and/or deafness) syndrome, mutations in the *CHD7* gene, the putative causative gene in CHARGE, have been investigated in KS and noted in a minority of patients who also tended to have additional features of the syndrome.

It is not surprising that the presence of anosmia in individuals with CHARGE syndrome predicts HH. A wide range of associated congenital anomalies have been reported in patients with KS, including cleft palate, hearing loss, color blindness, abnormal eye movements, unilateral renal agenesis, and synkinesia, although the relationship between these features and specific abnormalities of the *KAL* gene are unclear.

Gonadotropin-Releasing Hormone and Gonadotropin-Releasing Hormone Receptor Mutations. *GnRH*[111] and GnRH receptor gene mutations have been identified as a cause of familial isolated hypothalamic-pituitary hypogonadism.[112] These disorders affect both males and females, and olfaction is normal. Both homozygous and compound heterozygous cases occur. In those with biallelic mutations, the clinical phenotype is determined by the genetic burden defined by the more severe of the two mutations, unlike in those with a single mutation in whom this correlation does not hold, suggesting a role for genetic or environmental modifiers. As in KS, pulsatile GnRH administration may restore normal gonadal function and fertility in some patients with partially inactivating GnRH receptor mutations.

Another etiology for isolated hypothalamic-pituitary hypogonadism has been traced to autosomal recessive mutations in the *KISS1* and *KISS1R* genes. The *KISS1R* gene encodes an orphan G protein-coupled receptor that is a member of the rhodopsin family of receptors.[113] Mutations in the *KISS1R* gene, which can result in both absent and delayed puberty, are a less common cause of hypothalamic-pituitary hypogonadism than GnRH receptor mutations. Several consanguineous families have been identified, as well as one unrelated individual found to be a compound heterozygote for *KISS1R* mutations. As is the case with other causes of HH, fertility can be achieved with exogenous GnRH in men and women with *KISS1R* mutations.

The ligand of *KISS1R* is kisspeptin, a key regulator of hypothalamic GnRH release and pubertal onset. Thus, mutations in the *KISS1* gene also result in normosmic HH.[114]

Mutations in Pituitary Transcription Factors and Orphan Nuclear Receptors. Normal embryologic hypothalamic-pituitary development relies on a tightly regulated, complex cascade of tissue-, cell-, and stage-specific transcription factors. Mutations within the genes encoding for these transcription factors, therefore, may result in a spectrum of combined anterior pituitary hormone deficiencies and abnormal function of the hypothalamic-pituitary axis. While the etiology of many forms of hypopituitarism remains unknown, molecular genetic abnormalities in several pituitary transcription factors have now been elucidated.

Pit-1. The first identified transcription factor, pituitary-specific transcription factor (Pit-1), is essential for normal activation of the genes encoding for growth hormone (GH), prolactin, and TSH, as well as for normal differentiation and proliferation of the pituitary cell types responsible for the expression of these hormones.[115] Following its discovery in 1988, numerous additional transcription factors have been identified, some of which are also involved in normal function of hypothalamic GnRH and pituitary gonadotrophs.[116] Orphan nuclear receptors that regulate development within multiple levels of the HPG axis are also associated with hypothalamic-pituitary hypogonadism. Human genetic mutations that have been identified in these factors are discussed in the following sections.

Prop-1. Prop-1 (prophet of Pit-1) is a paired-like homeodomain transcription factor that is required for normal expression of Pit-1. *PROP1* mutations in humans are associated with GH, prolactin, and TSH deficiency in addition to LH and FSH deficiencies.[117] Pubertal progression has been quite variable in reported cases, with several individuals completing pubertal maturation before the development of permanent hypogonadism by their early twenties.

LHX3. Another etiology of combined pituitary hormone deficiency has been traced to mutations within *LHX3,* a pituitary transcription factor gene located on chromosome 9. Although a limited number of cases have been identified, all affected individuals have had gonadotropin deficiency and unresponsiveness to exogenous GnRH.[118]

LHX4. Heterozygous *LHX4* mutations are a rare cause of combined pituitary hormone deficiency and are associated with variable degrees of LH and FSH deficiencies.[119]

HESX1. Several different mutations within the transcription factor *HESX1* gene have been implicated in septooptic dysplasia associated with variable pituitary function. Although some patients exhibit apparently normal pituitary hormone secretion, a continuum ranging from isolated GH deficiency to panhypopituitarism has been described.[120] Studies from the mouse model have indicated that *HESX1* has an important role in embryologic development of the optic nerves and the hypothalamic-pituitary axis.

SOX2. Several heterozygous mutations have been described within the transcription factor *SOX2* gene. In addition to anophthalmia or severe microphthalmia, affected individuals have gonadotropin deficiency. Other associated findings include developmental delay, defect of the corpus callosum, esophageal atresia, and sensorineural hearing loss.[121]

DAX1. HH is a feature of X-linked adrenal hypoplasia congenita. The gene responsible for this condition, *DAX1,* encodes an orphan nuclear receptor that is expressed in adrenal, pituitary, hypothalamic, and gonadal tissue.[122] More than 100 different mutations within *DAX1* have been identified. Males with the disorder typically present with an adrenal crisis during infancy, whereas the hypothalamic-pituitary hypogonadism emerges in adolescence. However, there appears to be significant clinical variability among individuals with adrenal hypoplasia congenita. Congenital gonadotropin deficiency has been suggested by cryptorchidism in some newborns with *DAX1* mutations, while a normal minipuberty of infancy has also been reported in affected boys.[123] Atypical presentations have included hypothalamic-pituitary hypogonadism in a female with a homozygous *DAX1* mutation, delayed puberty in females with heterozygous mutations, and the delayed onset of adrenal insufficiency and hypogonadism in adolescence and adulthood in a few affected individuals.[124] Studies from the *Ahch* (*Dax1*) knockout mouse suggest that *DAX1* has a critical role in testis development and spermatogenesis, as well as in the function of the HPG axis. This finding, as well as recognition of the combined hypothalamic and pituitary defect in these patients, has been proposed to explain the disappointing results using exogenous GnRH or gonadotropins to induce virilization and fertility.[125]

SF1. Like *DAX1*, steroidogenic factor 1 *(SF1)* encodes an orphan nuclear receptor that regulates gene transcription in multiple tissues including the gonads, the adrenal glands, the hypothalamus, and the pituitary gland. The importance of *SF1* for normal gonadotrope function was first established by the knockout mouse, which exhibits gonadotropin deficiency and hypoplastic gonads. Human *SF1* mutations have been identified as a cause of 46,XY sex reversal and adrenal failure.[126] Some *SF1* mutations cause testicular dysgenesis without affecting adrenal function. Ovarian development appears to be normal thus far in a prepubertal girl with a heterozygous *SF1* mutation and adrenal insufficiency.

Mutations in Gonadotropins and Their Receptors. FSH and LH are composed of a common α subunit and a distinct β subunit and exert their biological effects through G protein-coupled receptors. No mutations of the α subunits have been described to date, but mutations of the FSH-β subunit, LH-β subunit, and gonadotropin receptor have been identified as causes of delayed puberty and abnormal reproductive function in males and females.[127] These mutations continue to provide important insight into the relative roles of FSH and LH in gonadal function and human physiology.

Follicle-Stimulating Hormone–β Subunit Mutations. Mutations in the FSH-β subunit gene have been reported to cause hypogonadism in both females and males.[128] The majority of cases have occurred in females with complete absence of pubertal development, although partial breast development in affected girls has been reported. The phenotype of males with *FSH-β* gene mutations ranges from delayed puberty and azoospermia to azoospermia alone.[129] As expected, serum LH levels are high in these patients, and FSH is undetectable.

Follicle-Stimulating Hormone Receptor Mutations. Homozygous inactivating mutations in the FSH receptor were first identified as the cause of autosomal recessive premature ovarian failure in several Finnish families.[130] The females in these kindreds demonstrated uneven degrees of pubertal development, followed by complete ovarian failure in association with elevated serum gonadotropins and hypoplastic ovaries. Subsequently, a number of novel FSH receptor mutations have been described in association with primary or secondary amenorrhea. In contrast, men with homozygous mutations have normal LH and testosterone levels and low-normal testicular volumes, with elevated FSH levels and unpredictable degrees of impaired spermatogenesis and infertility.[131]

Luteinizing Hormone–β Subunit Mutation. One case of delayed puberty because of an LH gene mutation has been described. The 17-year-old male proband was homozygous for a single base substitution in the LH-β subunit gene.[132] Serum LH was elevated, while FSH and testosterone levels were low. The finding of LH immunoreactivity with complete loss of LH bioactivity in this patient was consistent with the clinical phenotype. Three maternal uncles, all heterozygous for the same mutation, were infertile. Although female carriers appeared unaffected in this family, anovulatory infertility was reported in a woman with a novel mutation of the LH-β subunit.[133] Two novel mutations of the *LH* gene were described in a 31-year-old man with delayed puberty, azoospermia, and absent circulating LH. His sister, who carried the same mutations, had normal pubertal development and oligomenorrhea, indicating variable genetic expression in this condition.[134]

Luteinizing Hormone Receptor Mutations. Homozygous loss-of-function mutations of the LH receptor, inherited via autosomal recessive transmission, have been recognized as a rare cause of hypogonadism in males and females. The first such mutation was reported in two 46,XY individuals with female external genitalia but complete absence of breast development and primary amenorrhea.[135] Serum levels of LH were markedly elevated, while testosterone levels were low, and FSH levels were normal. Histologic examination of the testes revealed Leydig cell hypoplasia. Since then, multiple additional mutations of the LH receptor have been identified. Males with inactivating LH receptor mutations exhibit a clinical spectrum ranging from female external genitalia to hypospadias or micropenis. The testes are usually cryptorchid, and Müllerian structures are absent. In females, LH receptor mutations result in amenorrhea with normal secondary sexual development and elevations of LH and FSH. The finding of ovarian follicular development at all stages suggests that LH may be necessary for ovulation, but that follicular development may occur under the influence of FSH and ovarian paracrine factors alone.

A number of other gene defects associated with HH and neurological manifestations have been described, including defects in the *POLR3A/B* gene associated with 4H (hypomyelination, hypodontia and hypogonadotropic hypogonadism) syndrome, and defects in the *RNF216*, *OTUD4*, and *PNPLA6* genes causing ataxia and HH.[136,137]

Estrogen Receptor Defects. Some 19 years after it was discovered in a man, a homozygous mutation in the estrogen receptor alpha subunit causing estrogen resistance was reported in an 18-year-old woman. This specific mutation impaired estrogen signaling. The patient had no breast development and had significantly elevated estrogen levels and bilateral multicystic ovaries.[138] She had osteopenia and a delayed bone age (13.5 years) and no response to estrogen therapy.

Metabolism-Related Genetic Defects. Naturally occurring genetic mutations associated with obesity have indicated important interactions between metabolism and human reproduction. Hypothalamic-pituitary hypogonadism has been a feature of rare human mutations within the leptin gene and leptin receptor.[139] A similar phenotype was observed in a girl with primary amenorrhea and hypothalamic-pituitary hypogonadism in association with compound heterozygous mutations in prohormone convertase 1, an endopeptidase involved in neuropeptide processing. The precise role of these genes in GnRH release and/or function is unknown.

Chronic Disease. Any significant chronic disease or inflammation can result in delayed puberty, which is usually seen in association with poor growth and retarded skeletal maturation. Malnutrition also has a profound impact on gonadal function through loss of normal hypothalamic-pituitary pulsatile secretion. This is exemplified by the hypothalamic amenorrhea often observed in young women with anorexia nervosa, in whom chronic caloric restriction leads to aberrations in neuroendocrine function. The same phenomenon is observed in individuals engaging in frequent, high-intensity exercise such as runners or ballet dancers, in whom osteopenia is a common correlate. Hypothalamic-pituitary hypogonadism has also been documented in women of normal weight who practice severe restriction of dietary fat intake. Loss of GnRH pulsatility in these settings is likely the result of leptin deficiency, a hypothesis supported by the restoration of ovulatory cycles following human recombinant leptin administration in women with anorexia nervosa. These forms of hypogonadism are transient and characterized by a restoration of normal HPG function once the underlying abnormality is resolved.[140] In contrast, permanent hypothalamic-pituitary hypogonadism may result from acquired central nervous system insults such as infection, cranial irradiation, tumor, or trauma.

Syndromes. Hypothalamic-pituitary hypogonadism is a common feature of a number of different genetic syndromes with otherwise heterogeneous manifestations. For example, individuals with Prader–Willi syndrome often have hypogonadism secondary to hypothalamic-pituitary dysfunction.[141] Other syndromes that share this characteristic include Boucher–Neuhauser, Bardet–Biedl, and Noonan syndromes. Associated abnormalities often include cryptorchidism, micropenis, or both. Hypothalamic-pituitary hypogonadism also occurs in patients with pseudohypoparathyroidism type 1A in association with multiple hormone resistance from a loss-of-function mutation in the *GNAS1* gene.[142]

Primary Hypogonadism

Primary hypogonadism refers to conditions in which there is failure of normal sex steroid production because of an intrinsic abnormality of the gonads. Using traditional assays, individual gonadotropin levels in prepubertal children with primary hypogonadism may be indistinguishable from normal controls, with the development of elevated gonadotropins by the time pubertal age is reached. Using ultrasensitive methods, supranormal LH and FSH concentrations are detectable in prepubertal agonadal children of all ages compared with controls.[143] In contrast, serum inhibin B levels tend to be inversely proportional to gonadotropins in boys with primary gonadal failure.[144] The causes of primary hypogonadism include congenital and acquired gonadal abnormalities, as discussed in the next section.

Congenital Primary Hypogonadism

Chromosomal Abnormalities. It has been recognized for many years that normal ovarian activity depends on the presence and function of specific X chromosomal genetic loci. Therefore, abnormalities involving any significant portion of the X chromosome in females are associated with aberrant ovarian function. Varying degrees of gonadal dysregulation are also observed in males with an abnormal complement of X chromosomes. The most common karyotypic abnormalities leading to primary hypogonadism are discussed in the following sections.

Turner Syndrome. With an incidence of 1 in 2000 to 5000 liveborn females, Turner syndrome is the most common cause of primary ovarian failure. First described in 1938 by Dr. Henry Turner,[145] the syndrome consists of a missing or structurally abnormal X chromosome combined with characteristic phenotypic features. Although a wide range of physical characteristics may manifest, nearly 100% of affected individuals have short stature. Gonadal dysgenesis, as evidenced by "streak ovaries," is present in approximately 94% of patients and appears to occur as a consequence of accelerated oocyte atresia, with subsequent fibrosis of ovarian stroma. The multisystem involvement is demonstrated by the frequent occurrence of cardiac, renal, lymphatic, and musculoskeletal anomalies, while common phenotypic features include low-set, posteriorly rotated ears, high-arched palate, low posterior hairline, webbed neck, the appearance of widely spaced nipples, cubitus valgus, and hypoplastic, hyperconvex fingernails and toenails (Figs. 103.9, 103.10, and 103.11). Although many of these somatic characteristics may be the consequence of intrauterine lymphedema, the Turner syndrome phenotype in general is thought to result from a haploid dosage of genes on the X chromosome that normally escape X inactivation. Girls may come to medical attention in several ways. Lymphedema noted at birth may prompt an early diagnosis. Alternatively, girls may present in midchildhood or adolescence with progressive short stature or delayed puberty. Cytogenetic analysis reveals a heterogeneous group of X chromosomal abnormalities, with approximately 50% of patients exhibiting some form of mosaicism. The diagnosis of ovarian failure is based on the finding of elevated gonadotropins. These follow a diphasic pattern, with plasma LH and FSH levels rising during early and late childhood and exhibiting a nadir during middle years, although increased for age. FSH levels in young girls with Turner syndrome who have mosaic karyotypes are significantly lower than those in girls with monosomy X. Although the vast majority of patients will require exogenous

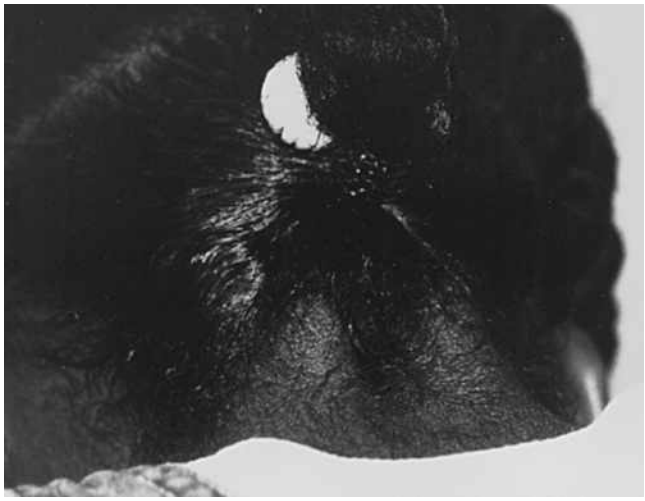

Fig. 103.9 Girls with Turner syndrome often have a low posterior hairline, which typically has a "tripartite" (double arch) configuration.

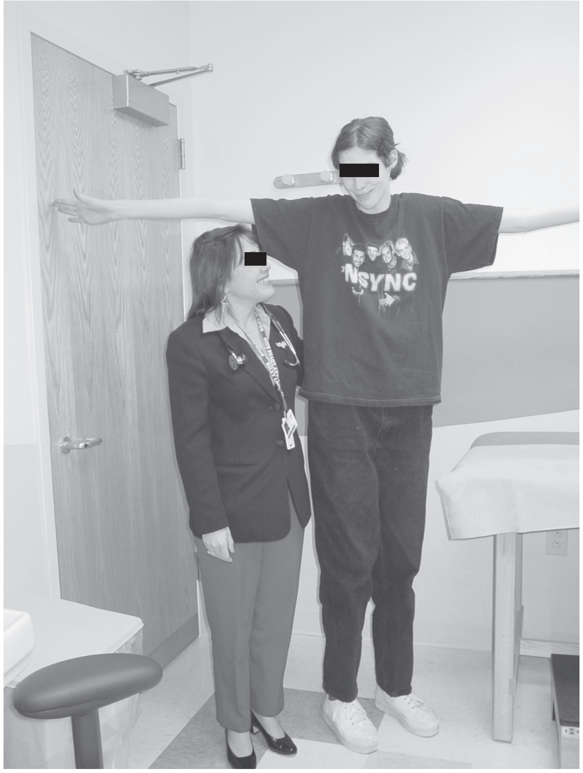
Fig.103.11 Complete absence of breast development in a 15-year-old girl presenting with delayed puberty. Arm span was 8.3 cm greater than height, and upper-to-lower body segment ratio was 0.7, confirming a "eunuchoid habitus." Karyotype was 46,XY.

sex-steroid replacement, approximately 30% of girls will experience spontaneous pubertal onset, and up to 16% percent will achieve menarche unassisted.[146] Rarely, women with Turner syndrome are able to conceive, although pregnancies in this population are complicated by a high incidence of fetal loss and congenital anomalies.[147]

Xq and Other Chromosomal Abnormalities. Patients with deletions or rearrangements of the long arm of the X chromosome typically have premature ovarian failure without phenotypic features of Turner syndrome. Molecular genetic analysis has led to the localization within the distal region of Xq of one or more genes essential for ovarian maintenance.[148] Many cases of sporadic X chromosome:autosomal translocations are also associated with premature ovarian failure, as are mutations within a forkhead transcription gene located on chromosome 3. Triple- and penta-X syndromes represent other examples of X chromosome aneuploidy in which premature ovarian failure is a frequent correlate (Fig. 103.12).



[redacted]

Fig. 103.12 Tall stature with increased arm span and primary ovarian failure in a 16-year-old girl with a 48,XXXX karyotype.

Klinefelter Syndrome. First described in 1942,[149,150] Klinefelter syndrome results from X chromosome polysomy in males, with the majority of patients demonstrating a 47,XXY karyotype. It is the most common disorder of the sex chromosomes, with an estimated incidence ranging from 1 in 400 to 1 in 1000 live-born males. Typical features include tall stature with eunuchoid body proportions, hypogonadism, a variety of learning and behavioral problems, and borderline-to-normal intelligence. The testes, which are usually small and firm and may be cryptorchid, are characterized by seminiferous tubule dysgenesis and a spectrum of Leydig cell dysfunction. Although pubertal onset may occur normally, serum testosterone levels are generally at the low end of the normal range, and inhibin B levels gradually decrease in conjunction with progressive testicular failure. Gynecomastia, because of an abnormal estrogen/androgen ratio, and elevated serum gonadotropins are important clues to the presence of Klinefelter syndrome in a boy at pubertal age. However, many patients remain undiagnosed through adolescence and may present in adulthood with infertility, azoospermia, or hypogonadism.[150] A propensity for the development of certain malignancies has long been recognized in individuals with Klinefelter syndrome. Breast cancer, historically believed to occur at increased frequency, has not been observed in other large series, whereas germ cell tumors have been found to be 50 times more common in this population and have been implicated in rare cases of precocious puberty in boys with Klinefelter syndrome.[151]

Enzymatic Defects in Steroid Biosynthesis. Although the most common forms of CAH (see Chapter 94) are associated with an excess of adrenal androgen secretion, rare defects exist in which there may be a complete inability to synthesize both androgens and estrogens. These

TABLE 103.3 Clinical, Laboratory, and Radiographic Data in a Patient With Pure 46,XY Gonadal Dysgenesis

Clinical Characteristics	Laboratory Data	Radiographic Studies
• Presenting complaint: primary amenorrhea • Chronologic age: 15 years • Height: 162.7 cm (50th percentile on female growth chart, 25th percentile on male growth chart) • Arm span: 171 cm • Upper/lower ratio: 0.7 • Tanner staging: Breasts: I Pubic hair: II • External genitalia: normal female	• LH: 15.8 mIU/mL (1.0–18) • FSH: 64.7 mIU/mL (4–13) • Estradiol: 13 pg/mL (10–178) • Thyroxine: 7.6 μg/dL (4.5–12) • TSH: 3.9 μIU/mL (0.45–6.0) • Prolactin: 10.7 ng/mL (5.3–22) • Karyotype: 46,XY • MIS: 0 ng/mL	• Bone age x-ray: 11.6/12 years • Pelvic ultrasound: small uterus, no visible gonads • Genitogram: normal vagina with cervical impression

LH, Luteinizing hormone; *FSH*, follicle-stimulating hormone; *TSH*, thyroid-stimulating hormone; *MIS*, Müllerian-inhibiting substance.

include deficiencies of 17α-hydroxylase and 17,20-lyase enzymes, as well as a deficiency of the steroidogenic acute regulatory protein, which plays a key role in cholesterol transport, the rate-limiting step of steroid hormone biosynthesis.[152] Lipoid adrenal hyperplasia results from mutations within the steroidogenic acute regulatory gene, with many different mutations identified to date.[153] Clinical manifestations consist of severe electrolyte imbalance usually beginning in infancy, as well as complete deficiency of adrenal and testicular steroidogenesis, resulting in phenotypically female genitalia in both sexes. A fascinating aspect of lipoid adrenal hyperplasia is that some affected 46,XX individuals experience spontaneous puberty and normal menstrual cycles, presumably owing to steroidogenic acute regulatory-independent steroidogenesis within the ovary. Mutations in the *CYP17* gene (responsible for both 17α-hydroxylase and 17,20-lyase activity) is another rare cause of delayed puberty in males and females. Both sexes appear phenotypically female, with affected males demonstrating absence of Müllerian structures and intraabdominal testes. Diagnosis is based on extreme elevations of adrenal steroid precursors, and treatment consists of glucocorticoid and sex steroid replacement as indicated by the phenotypic sex. Genetic males with severe 17α-hydroxylase deficiencies are, therefore, typically raised as females, using estrogen therapy to induce breast development at puberty once the diagnosis is made.

Disorders of Sex Development. Abnormalities of sexual determination and differentiation result in a number of conditions typified by either overvirilization of genetic females or undervirilization of genetic males, and are usually associated with genital ambiguity (see Chapter 101). However, rare disorders exist in which a phenotypically normal appearance is present, which may result in delayed diagnosis until abnormal pubertal development prompts medical evaluation. Discussion of these disorders will be limited to genetic males, who may appear phenotypically female, as discussed in the following sections.

Complete Androgen Insensitivity. A variety of mutations within the androgen receptor gene may result in qualitative or quantitative abnormalities in androgen receptor function.[154] Although partial androgen insensitivity is a cause of undervirilization in a male infant, complete androgen insensitivity results in an apparently normal female phenotype in a 46,XY individual. These patients are typically tall and present in adolescence with normal breast development, primary amenorrhea, and a paucity of pubic and axillary hair. The external genitalia are those of a normal female, although the vagina ends blindly. The testes are intraabdominal, and no female internal reproductive organs are found. As in XY gonadal dysgenesis, women with complete androgen insensitivity are at risk for gonadal neoplasms, although the incidence appears to be low in this setting. Therefore, most clinicians advocate leaving the gonads in place until pubertal development is complete, after which time gonadectomy is recommended, and estrogen replacement is necessary to maintain secondary sexual characteristics.

Pure 46,XY Gonadal Dysgenesis (Swyer Syndrome). First described in 1955,[155,156] pure 46,XY gonadal dysgenesis manifests as a normal female phenotype with complete absence of secondary sexual development (see Fig. 103.11; Table 103.3). Stature is normal to tall, and there are no stigmata of Turner syndrome. A uterus and fallopian tubes are usually present, and the gonads are characterized by fibrotic "streaks." Heritable forms of pure 46,XY gonadal dysgenesis exist, with postulated modes of transmission including X-linked and autosomal inheritance patterns. Although the causes of gonadal dysgenesis are largely unknown, approximately 15% of patients harbor mutations within *SRY*. Additional etiologies implicated in pure XY sex reversal include deletions or mutations in genes involved in male sex determination, including *SOX9, SF1, WT1,* and *DAX1*.[156] Regardless of the precise genetic cause, patients with pure 46,XY gonadal dysgenesis require prophylactic gonadectomy because of an estimated 20% to 30% incidence of gonadoblastoma or dysgerminoma in this population.[157]

Testicular Regression (Vanishing Testes) Syndrome. *Testicular regression syndrome* refers to a rare condition in which the testes become nonfunctional and involute (thus the term *vanishing*) at some point during intrauterine life or the early postnatal period. Depending on the timing of testicular regression, ambiguous or normally formed male genitalia may result. The cause of testicular regression is poorly understood but is hypothesized to be the result of a vascular insult to the testes during intrauterine life. Familial cases have rarely been reported. Males may go undiagnosed until adolescence or even adulthood. An hCG stimulation test is useful in the evaluation of Leydig cell function, while Müllerian-inhibiting substance (antimüllerian hormone) levels, secreted by Sertoli cells, provide additional information regarding the presence and integrity of testicular tissue. There is controversy whether inguinal exploration of these patients is always mandatory, as the incidence of residual gonadal tissue is extremely low.[158]

Acquired Primary Hypogonadism. There are several causes of acquired primary hypogonadism, all stemming from significant insult or injury to the gonads. Although trauma and torsion represent rare causes of acquired primary hypogonadism, improved survival rates of childhood cancer have resulted in a rise in cases of primary hypogonadism occurring as sequelae of irradiation, chemotherapy, and bone marrow transplantation. Autoimmune-related gonadal failure is a feature of type I and type II polyglandular autoimmune syndromes and may have an insidious onset many years after the development of adrenal insufficiency. Conversely, ovarian failure may be the first presenting sign of these disorders, and, as such, girls with unexplained premature ovarian failure should be screened for other autoimmune disorders. Metabolic diseases associated with acquired gonadal failure include galactosemia, where premature ovarian failure may occur in up to 60% of affected females and result in complete or partial lack of pubertal development.[159]

KEY POINTS

- Constitutional delay of growth and puberty is a well-described variation of normal pubertal development that is the most common cause of delayed puberty in both boys and girls. Evidence suggests genetic predisposition with an autosomal dominant effect in addition to environmental modifiers.
- Short-term low-dose anabolic therapy in boys and estrogens in girls is effective in promoting growth and pubertal development without advancing bone age.
- Pathologic causes of delayed puberty encompass two categories: conditions associated with hypothalamic-pituitary hypogonadism and those associated with hypergonadotropic or primary hypogonadism.
- Single-gene defects are estimated to account for 30% of patients with hypothalamic-pituitary hypogonadism.
- Kallmann syndrome is the prototype of gonadotropin-releasing hormone deficiency and refers to the association between hypogonadotropic hypogonadism and anosmia. Sporadic cases and multiple heritable forms have been described, including the X-linked form caused by mutations in the *KAL* gene.
- Turner syndrome and Klinefelter syndrome are the most common karyotypic abnormalities leading to primary hypogonadism.

TREATMENT OF DELAYED PUBERTY

The goal of therapy in children with hypogonadism is to initiate secondary sexual development in a way that simulates normal puberty. This is achieved by using low doses of sex steroids at initiation of therapy and gradually increasing the dosage over time. Once pubertal development is complete, adult replacement doses of gonadal steroids are required for the maintenance of secondary sexual characteristics and normal sexual function.

Girls

Multiple protocols exist for estrogen replacement therapy. These include transdermal estrogen or oral conjugated or unconjugated estrogen preparations, all of which are initiated at very low doses. Concurrently monitoring growth, skeletal maturation, and pubertal progression, the dose of estrogen is then gradually increased at 6- to 12-month increments to an adult replacement dose. Once breakthrough bleeding or Tanner stage IV breast development has been achieved, progesterone is added in the form of medroxyprogesterone acetate or micronized progesterone, which allows for the commencement of monthly bleeding. Once puberty is complete, oral contraceptive pills offer a convenient method of combined estrogen-progesterone therapy. A salutary effect of very-low-dose estrogen on growth has been observed in Turner syndrome, and the optimal estradiol replacement regimen in hypogonadal girls remains under investigation. As has been observed in hypogonadal boys, sex steroid replacement in girls with hypogonadism significantly improves calcium absorption and retention, with important implications in terms of the acquisition of bone mineral density.[160]

Boys

The most commonly employed method of sex steroid replacement therapy in adolescent hypogonadal boys consists of IM depot preparations of testosterone such as testosterone enanthate or cypionate. The typical starting dose is 50 to 100 mg IM or SC every 4 weeks, which is followed by gradual increases of 25 to 50 mg every 6 to 12 months as indicated by rates of growth, skeletal maturation, and pubertal progression. An adult replacement dose of testosterone consists of 200 to 250 mg IM or SC every 2 to 4 weeks, resulting in elevation of serum testosterone levels to within the normal range. Alternate forms of maintenance testosterone replacement include transdermal testosterone patches and testosterone gels. Although experience with these preparations during adolescence is limited, ongoing investigation may reveal that they are safe and effective for pubertal induction.[161]

KEY POINTS

- Treatment of pathologic causes of delayed puberty is with sex steroids, using low doses at initiation of therapy and gradually increasing the dosage over time to simulate normal puberty.

CONCLUSION

In summary, causes of precocious and delayed puberty include both normal variants and abnormalities at any level of the HPG axis. An increasing number of molecular genetic abnormalities have been linked to specific forms of precocious puberty and hypogonadism. Treatment of precocious puberty depends on the specific etiology. Sex steroid replacement leads to successful pubertal induction and the acquisition of adult secondary sexual development in those with hypogonadism.

REGULATION OF GONADOTROPIN

The Gonadotropins

The gonadotropin hormones, luteinizing hormone (LH), and follicle-stimulating hormone (FSH), are secreted by specialized cells (gonadotrophs) within the anterior pituitary gland. The secretion of LH and FSH is orchestrated by hypothalamic activity. Gonadotropin-releasing hormone (GnRH) is released from the median eminence of the hypothalamus via the hypophyseal-portal circulation to stimulate gonadotropin secretion. LH and FSH are glycopeptides each consisting of a common α-subunit, and a unique LH-β or FSH-β subunit, respectively. The secretory patterns of LH and FSH have two components, basal and pulsatile. The pituitary secretes tonic (basal) levels of each hormone with superimposed burst of secretion (pulsatile) every 60 to 90 minutes, which is stimulated by the pulsatile GnRH secretion. LH has a more pronounced pulsatile component than FSH, which has a greater component of basal secretion. Push-pull perfusion frequent sampling of the hypophyseal-portal circulation in monkeys has determined that pulses of LH, FSH secretion are entirely dependent on and coincident with hypothalamic GnRH secretion.[1] The frequency of GnRH pulses regulates the ratio of LH to FSH secretion. High GnRH pulse frequencies increase α-subunit and LH-β subunit transcription, thus favoring LH secretion; conversely, low GnRH pulse frequency favors FSH-β gene transcription and FSH secretion.[2]

Gonadotropin-Releasing Hormone

The Nobel Prize-winning isolation of GnRH from hypothalamic porcine extracts and discovery of its potent action to stimulate LH secretion heralded the conceptualization of the hypothalamo-pituitary-gonadal (HPG) or reproductive axis.[3] Several isoforms of GnRH exist and are distributed throughout the mammalian central nervous system (CNS), but only the GnRH I isoform has a known, direct role in regulating gonadotropin secretion. During embryogenesis, GnRH I neurons migrate caudally from the olfactory placode to the basal forebrain, under spatiotemporal regulation by several proteins such as those involved in fibroblast growth factor (FGF) and prokineticin signaling, adhesion molecules such as anosmin-1 (the product of KAL gene), and heparin sulfate glycosaminoglycan compounds (Fig. 105.1).[4] Craniofacial tissues and olfactory ensheathing cells also play important roles in neurogenesis and migration of the GnRH neurons.[4,5] Only 1000 to 2000 GnRH neuronal cell bodies are distributed postnatally within regions of the basal forebrain, particularly the preoptic area (POA). GnRH neuronal axons terminate at the median eminence, which has a fenestrated area of blood-brain barrier, enabling GnRH secretion into the hypophyseal-portal circulation. Failure of appropriate embryonic migration of GnRH neurons leads to congenital hypogonadotropic hypogonadism (CHH, low levels of gonadotropins and sex steroids) associated with anosmia, termed Kallmann syndrome.[4] Failure of GnRH activation (with normal migration), its regulation, or its action on the gonadotroph such as that associated with mutations in GnRHR, GNRH1, KISS1R, leptin, or leptin receptor, Tachykinin 3 (TAC3), TACR3, causes normosmic CHH.[4,5] Some mutations, such as those in PROK2, PROKR2, FGFR1, FGF8, SEMA3A, and CHD7, have been associated with both anosmic and normosmic forms of IHH.[4]

Pubertal Onset of GnRH Secretion. After a brief period of activity during the neonatal period, GnRH secretion from specialized neurons in the medial POA (in rodents and sheep) or mediobasal hypothalamus (in primates) remains quiescent throughout juvenile life.[6] Subsequently, a surge in the pulsatile release of GnRH into the

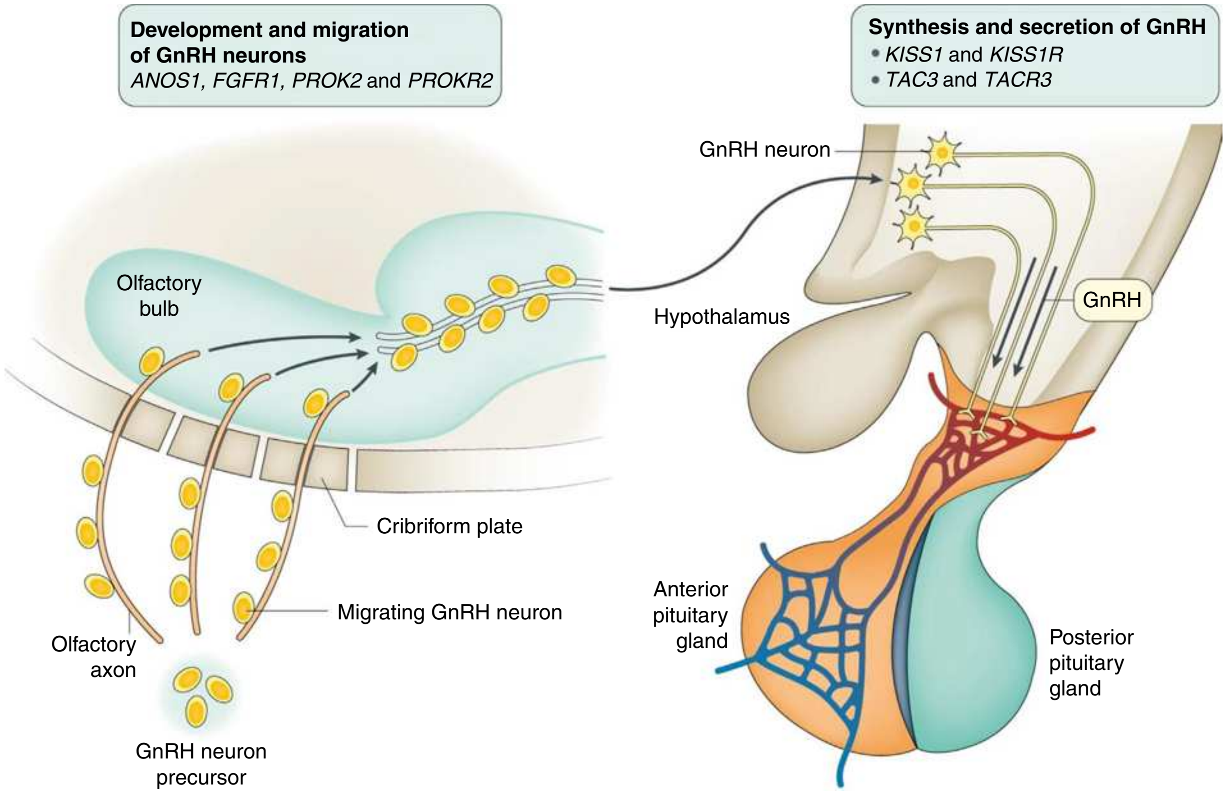

Figure 105.1 Migration of gonadotrophin-releasing hormone (GnRH) neurons during embryogenesis. During embryogenesis, GnRH neuron precursors originating within the olfactory placode migrate caudally to the hypothalamus. Several neurotrophic factors including prokineticin 2 (PROK2), the prokineticin 2 receptor (PROKR2), anosmin-1 (ASOS1), and fibroblast growth factor receptor 1 regulate spaciotemporally the migration of GnRH neurons. Failure of migration of GnRH neurons causes a congenital hypogonadotropic hypogonadism (CHH) with anosmia (Kallmann syndrome). Synthesis and secretion of GnRH is regulated by factors including kisspeptin (KISS1) and its receptor (KISS1R), neurokinin B (TAC3), and the neurokinin 3 receptor (TACR3). Failure of activation of GnRH neurons following normal migration is termed normosmic CHH. GnRH neurons terminate at the median eminence that has an incomplete blood-brain barrier, allowing GnRH to be released into the hypophyseal-portal circulation to reach the anterior pituitary gland. (From Salonia A, Rastrelli G, Hackett G, et al. Paediatric and adult-onset male hypogonadism. *Nat Rev Dis Primers*. 2019;5(1):38.)

hypothalamo-pituitary portal circulation heralds the onset of puberty.[7] GnRH stimulates the pulsatile release of LH and FSH to stimulate gonadal maturation and sex steroid secretion to mediate pubertal maturation and sex-specific physical characteristics.

The GnRH Pulse Generator. Pioneering studies by Knobil unveiled the critical requirement for pulsatile pattern of GnRH secretion to maintain physiological gonadotropin secretion.[8] Constant infusion of synthetic GnRH fails to stimulate gonadotropin release in monkeys with hypogonadotropic hypogonadism due to lesioning of the hypothalamus; however, hourly pulses of GnRH restore pituitary gonadotropin secretion in these animals.[8] Although an intermittent pattern of GnRH release may be observed from the cultured GnRH neurons, their activity is extensively modified by a network of neurohumoral signals. The hypothalamic elements responsible for the physiological pattern of pulsatile GnRH secretion are collectively referred to as the "GnRH pulse generator." Several candidate components of the GnRH pulse generator have been identified[1] and are listed in Table 105.1.[9] The relative balance of these factors determines the pubertal onset and subsequent pulsatile secretion of GnRH and gonadotropin secretion. Disruption of excitatory or modulatory inputs to the GnRH pulse generator such as kisspeptin or neurokinin B may cause hypogonadotropic hypogonadism. Similarly, overactivation of inhibitory components of the GnRH pulse generator such as excessive dynorphin (an endogenous opioid) causes hypogonadotropic hypogonadism.

Kisspeptin as a Regulator of Gonadotropin Secretion. Kisspeptin is a group of RF-amide peptides encoded by the KISS1 gene, which signals via the G-protein-coupled Kisspeptin receptor. Multiple kisspeptin isoforms have been identified; kisspeptin-54 is the major circulating isoform in humans.[10] Expression of kisspeptin and its receptor has been identified in two major neuronal populations within the hypothalamus of rodents: in the arcuate nucleus (ARC) and the anteroventral periventricular nucleus (AVPV).[11] In humans and primates, kisspeptin mRNA is predominantly expressed within the infundibular nucleus (equivalent of the ARC in this order of mammals). Kisspeptin neurons project to GnRH neuronal terminals in the median eminence.

Inactivating mutations in the gene encoding kisspeptin and its receptor cause pubertal failure.[12] Kisspeptin receptor null mice have hypogonadotropic hypogonadism (HH), as suggested by low levels of circulating gonadotropin hormones, with small testes in male mice and a delay in vaginal opening and an absence of follicular maturation in female mice. Administration of exogenous GnRH corrected the HH phenotype observed with inactivation of kisspeptin signaling, which is consistent with the view that kisspeptin acts by stimulating endogenous GnRH. Conversely, activation of kisspeptin signaling

TABLE 105.1 Neurotransmitters Which Modulate Gonadotropin-Releasing Hormone (GnRH) Release

Excitatory	Inhibitory	Excitatory, Inhibitory, or Modulatory
Glutamate	Corticotrophin-releasing hormone	Dopamine
Neuropeptide Y	GABA	Acetylcholine
Substance P	Dynorphin	Oxytocin
Kisspeptin	Serotonin	Vasopressin
Histamine		Neurokinin B
Vasoactive intestinal peptide		
Galanin		
Dopamine		
Noradrenaline		
Cholecystokinin		

Candidate factors have been classified as being excitatory, inhibitory, or both excitatory and inhibitory on GnRH release. *GABA,* gamma-aminobutyric acid.

induces precocious puberty in rodents. Furthermore, activating mutations in the kisspeptin receptor gene have been identified in girls with precocious puberty.[13] In several mammalian species, administration of intracerebroventricular or intravenous kisspeptin has been shown to acutely and potently increase LH and FSH secretion in males and females by stimulating GnRH secretion. Furthermore, intravenous or subcutaneous injection of kisspeptin potently increases LH and FSH in men and women with or without hypogonadism.[14,15] In summary, kisspeptin is a direct and potent stimulator of endogenous GnRH secretion, which gives it potential to treat patients with reproductive disorders in the future.

It has been proposed that kisspeptin may also have direct effects on the anterior pituitary gland to stimulate the release of LH and FSH. Both the KISS1 and KISS1R genes are expressed in pituitary gonadotrophs. The addition of kisspeptin results in dose-dependent LH secretion from cultured pituitary cells and tissue explants.[16] However, kiss1r$^{-/-}$ mice display the phenotype of hypogonadotropic hypogonadism and respond to exogenous GnRH with an appropriate LH response. In addition, intravenous administration of kisspeptin fails to stimulate LH release in GnRH-replaced, ovariectomized ewes in which the hypothalamus and the pituitary have been disconnected. In summary, a direct action of kisspeptin on the pituitary is plausible, but its physiological importance remains unclear.

Neurokinin B and Dynorphin as Regulators of Gonadotropins.

NKB and DYN are coexpressed with kisspeptin within the ARC; these neurons are commonly referred to as kisspeptin/neurokinin B/dynorphin (KNDy) neurons (Fig. 105.2). Like kisspeptin, NKB and DYN play important regulatory roles in mammalian reproduction. Mutations in the genes encoding NKB, TAC3, or its receptor (TACR3) are associated with hypogonadotropic hypogonadism.

The role of NKB in GnRH pulse regulation remains controversial in part due to the variable effects of exogenous NKB administration on LH secretion depending on the animal model. Peripheral administration of NKB in healthy humans has no effect on gonadotropin release. The heterogeneity of observed effects of NK3R agonism in different experimental models may arise due to differences in the steroid hormone milieu during NKB administration.

Exogenous opioids profoundly lower LH and FSH and inhibit LH pulsatility. It is now thought that exogenous opioids act by mimicking the effects of DYN, an endogenous opioid peptide that acts primarily through the κ-opioid receptor (KOR).[17] It has been proposed that DYN may act in an autocrine manner to negatively regulate KNDy neurons that express KOR, rather than directly acting upon GnRH neurons, few of which express KOR.[18]

In summary, KNDy neurons have complex and powerful effects to regulate human reproduction. Kisspeptin activates GnRH secretion, and DYN is autoinhibitory. NKB signaling is obligatory for GnRH activation, but its precise physiological role remains unclear.

KEY POINTS

- Pulsatile secretion of gonadotropin-releasing hormone (GnRH) stimulates luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion, but constant infusion of GnRH paradoxically inhibits LH and FSH secretion.
- Low levels of circulating estradiol suppress LH and FSH secretion, but high levels stimulate an LH surge to trigger ovulation in women.
- KNDy neurons in the preoptic area of the hypothalamus coexpress kisspeptin, neurokinin B, and dynorphin and mediate the negative feedback effects of testosterone, estradiol, and progesterone by inhibition of kisspeptin release.

Feedback on Gonadotropin Secretion by Sex Steroids

Estrogen Feedback. In mammals, estradiol has biphasic effects on GnRH secretion. Low levels of circulating estrogen suppress gonadotropin secretion, but at mid-cycle, high circulating levels of estrogen (from the dominant ovarian follicle) exert a potent positive feedback effect, leading to a surge in the plasma LH and ovulation. ERα is critical for the positive feedback effect of estrogen, which results in the female mid-cycle LH surge. Adult female rodents pre-administered an ERα antagonist fail to ovulate or undergo a preovulatory LH surge and have blunted LH response following administration of kisspeptin-10.[19] Conversely, the preovulatory LH surge is preserved in ERβ knockout mice and rats administered an ERβ antagonist.

GnRH neurons lack estrogen receptor alpha (ERα), which suggests the existence of an intermediary neuronal pathway for mediating estrogen feedback.[20] Kisspeptin is now known to play a critical role in mediating the effects of estrogen on GnRH to mediate the LH surge. Kisspeptin expression in the AVPV of rats is the highest during the evening of proestrus when the LH surge occurs, whereas expression levels in the ARC are at their lowest during this time.[21] In addition, kisspeptin expression is increased in the AVPV at the time of estrogen and progesterone-induced LH surge in ovariectomized rats, but ARC kisspeptin expression is at its lowest during this time (Fig. 105.3).[21] Furthermore, kisspeptin neurons in the AVPV coexpress a surrogate marker of cellular activation, Fos, at the time of the LH surge, whereas minimal Fos expression was observed on diestrus; in contrast, ARC kisspeptin neurons do not express Fos during the LH surge or on diestrus. Finally, most kisspeptin neurons in both the AVPV and ARC express ERα. Blockade of hypothalamic kisspeptin signaling by intracerebroventricular injection by the pharmacological antagonist is sufficient to prevent ovulation in rodents.[22] Taken together, these data provide compelling evidence that a subpopulation of kisspeptin signaling in the AVPV is activated by circulating estrogen to generate the preovulatory LH surge in rats.

The epigenetic regulation of kisspeptin gene expression in mediating the estrogen-positive feedback action has been investigated

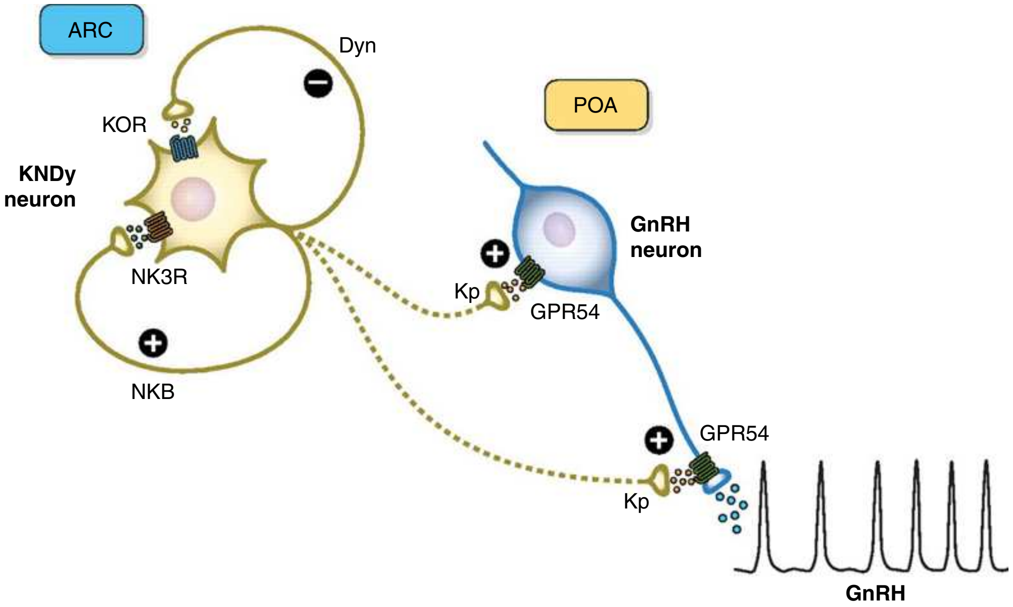

Figure 105.2 The role of kisspeptin-neurokinin B-dynorphin (KNDy) neurons in the control of pulsatile gonadotrophin-releasing hormone (GnRH) secretion. The physiological, pulsatile pattern of GnRH is critical to its ability to stimulate gonadotrophin secretion. KNDy neurons may play an important role in GnRH activation and pulse generation. A population of KNDy neurons within the hypothalamic ARCuate nucleus projects to GnRH neuronal cell bodies and terminals within the preoptic area (POA). KNDy neurons are the major driving signal for GnRH pulsatile release. Kisspeptin released from KDNy neuronal terminals signals via the kisspeptin receptor (GPR54) to potently activate GnRH neuronal activity, leading to GnRH secretion, which stimulates gonadotropin secretion. NKB signals via the neurokinin 3 receptor (NK3R) and is implicated in GnRH pulse initiation, possibly autoactivating KNDy neurons. Conversely, DYNorphin signals via the kappa opioid receptor (KOR), which may mediate GnRH pulse termination by autoinhibition of KNDy neurons. (Adapted from Pinilla L, Aguilar E, Dieguez C, Millar RP, Tena-Sempere M. Kisspeptins and reproduction: physiological roles and regulatory mechanisms. *Physiol Rev*. 2012;92(3):1235–316. doi: 10.1152/physrev.00037.2010.)

in mice. In the mouse AVPV, there is a high degree of acetylation at the histone of kisspeptin gene locus while the same locus in the ARC showed histone deacetylation in response to estrogen.[23] This suggests that epigenetic regulation of kisspeptin contributes to the activation of kisspeptin signaling in the AVPV in response to estrogen underpinning the LH surge.[23]

Testosterone Feedback. Unlike estrogen which has biphasic effects on gonadotropins, testosterone suppresses LH and FSH secretion in most physiologic conditions. GnRH neurons do not express the androgen receptor (AR). Furthermore, reduced levels of testosterone are associated with increased LH and FSH pulse frequency, suggesting that testosterone inhibits GnRH secretion.[24] Kisspeptin neurons within the hypothalamic ARC have been implicated in mediating the negative feedback regulation of GnRH secretion by circulating testosterone. Orchidectomy normally elevates LH and FSH due to reduced negative testosterone feedback; this is prevented by the administration of a selective kisspeptin antagonist. Aromatization to estradiol may partially mediate the negative feedback upon kisspeptin signaling by testosterone as dihydrotestosterone is less effective at suppressing Kiss1 ARC kiss1 mRNA than testosterone or estradiol in rodents.[25]

When the action of GnRH on the gonadotrophs is blocked by a GnRH antagonist, testosterone directly and selectively increases pituitary FSH secretion.[26] Thus, in male rats treated with a GnRH antagonist, graded doses of testosterone are associated with a dose-dependent increase in serum FSH[26] and upregulation of FSH-β mRNA levels,[27] whereas serum LH remains suppressed.

Metabolic Regulation of Gonadotropins

The availability of adequate nutrition is obligatory for fertility. The signals linking body weight, energy stores, and body composition with fertility have been extensively studied. Leptin is a peptide hormone secreted by adipocytes that circulates in proportion to fat mass. Disruption of leptin secretion (e.g., in *ob/ob* mice) or action (*db/db* mice) results in delayed puberty and hypogonadotropic hypogonadism in mice and humans. Furthermore, leptin administration reverses infertility associated with leptin deficiency.[28] Thus, leptin is an important humoral link between nutrition and fertility.

However, GnRH neurons lack receptors for the major metabolic signaling peptides, including insulin and leptin. Kisspeptin has been implicated as an intermediary between leptin signaling and GnRH function. *Ob/Ob* mice have reduced ARC levels of kisspeptin mRNA compared with wild-type controls,[29] and kisspeptin expression is increased following exogenous leptin administration. Fasting reduces hypothalamic kisspeptin mRNA and delays the onset of puberty in rats. In addition, central administration of kisspeptin to chronically undernourished prepubertal rats restores sexual maturation. However, only a small fraction of kisspeptin neurons express the leptin receptor, and genetic disruption of the leptin receptor in kisspeptin neurons does not inhibit reproduction in rodents suggesting the presence of additional circuits of leptin-responsive neurons involved in the metabolic control of GnRH neuronal activity that modulate the kisspeptinergic tone.[30]

To characterize the leptin-responsive neurons that mediate the effects of energy homeostasis on reproductive function in female mice, Martin et al.[31] selectively ablated the leptin receptor in neurons that were predominantly inhibitory (GABAergic) or excitatory (glutamatergic). They found that the ablation of leptin receptors in GABAergic neurons, but not in glutamatergic neurons, delayed sexual maturation and impaired reproductive function and fertility.[31] These data suggest that leptin-responsive GABAergic neurons are involved in conveying signals of energy balance via kisspeptin neurons to regulate reproductive function.

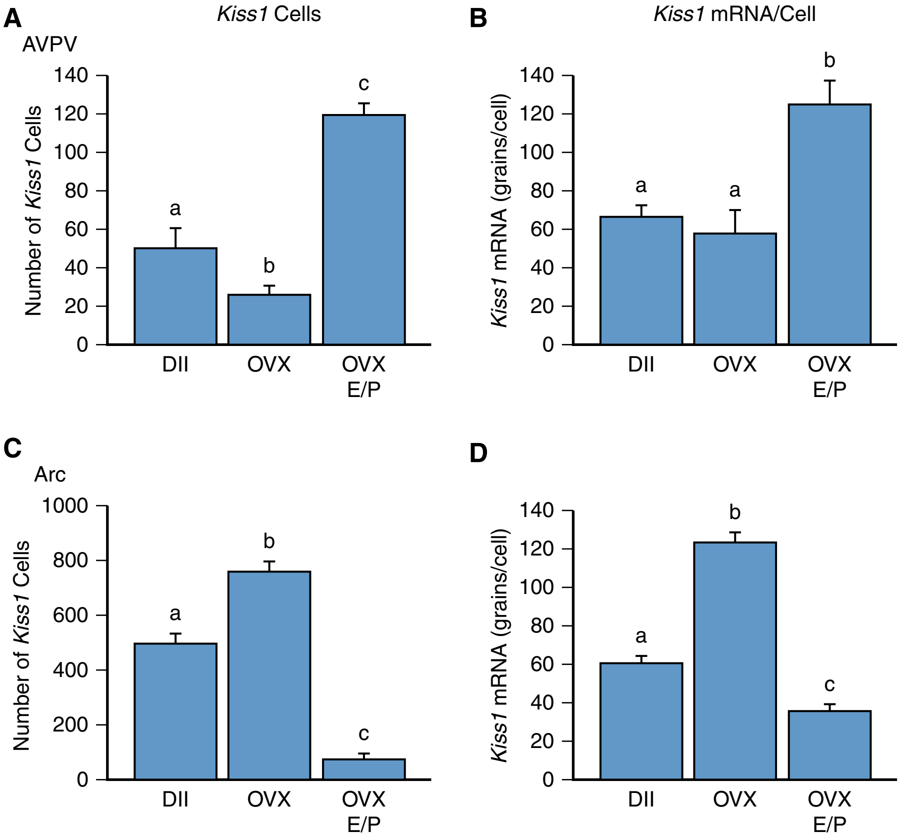

Figure 105.3 Distinct subpopulations of hypothalamic kisspeptin neurons mediate positive and negative feedback of estradiol in rats. **A-B**, In the hypothalamic anteroventral periventricular nucleus (AVPV), ovariectomy (OVX) *reduces* the number of kiss1-positive cells (**A**) and levels of kiss1 expression per cell (**B**). Conversely, experimental induction of the luteinizing hormone (LH) surge (OVX E/P) potently increases the number of kiss1-positive cells and levels of kiss1 expression within the AVPV. Collectively, these data suggest that kisspeptin signaling within the AVPV may mediate the positive feedback by estradiol associated with the LH surge. **C-D**, In the hypothalamic ARCuate nucleus, OVX increases the number of kiss1-positive cells (**C**) and levels of kiss1 expression per cell (**D**). Conversely, experimental induction of the LH surge (OVX E/P) reduces the number of kiss1-positive cells and suppresses kiss1 expression within the ARC. Collectively, these data suggest that kisspeptin signaling within the ARC may mediate negative feedback by estradiol on gonadotropin secretion. Values without common notations (a, b, c) differ significantly ($P < 0.05$). Values are the mean ± SEM. *DII,* Diestrus. (Smith JT, Popa SM, Clifton DK, Hoffman GE, Steiner RA. Kiss1 neurons in the forebrain as central processors for generating the preovulatory luteinizing hormone surge. *J Neurosci.* 2006;26(25):6687–6694. doi: 10.1523/JNEUROSCI.1618-06.2006.)

In contrast to leptin, the regulatory role of insulin in mammalian reproduction is currently unclear due to conflicting experimental data. Multiple studies have demonstrated that streptozotocin-induced insulin deficiency causes hypogonadotropic hypogonadism,[32] and type 1 diabetes is commonly associated with hypogonadotropic hypogonadism. A role for insulin signaling in the central regulation of reproduction is implied by observing that brain-specific deletion of insulin receptors in (NIRKO) mice causes hypogonadotropic hypogonadism.[33] However, specific deletion of the insulin receptor from either GnRH or kisspeptin neurons results in no obvious reproductive phenotype.[34] Taken together, insulin deficiency profoundly impacts gonadotropin secretion but has no obvious, direct effects on GnRH or kisspeptin signaling. The critical locations of insulin-sensitive targets within the brain influencing the reproductive system are therefore an important, unanswered question.

Kisspeptin cells communicate with neuropeptide Y (NPY) and proopiomelanocortin (POMC) cells, and this network of kisspeptin, NPY, and POMC neurons are involved in the coordination of brain control of reproduction and energy homeostasis.[35] NPY is an orexigenic peptide known to increase food intake, while POMC is a precursor of α-melanocyte–stimulating hormone (α-MSH), known for its anorectic effects. Neurons expressing NPY and POMC are in close apposition with kisspeptin neurons in the ARC.[35] Furthermore, central administration of an α-MSH agonist results in increased kisspeptin mRNA in the POA and increased plasma LH levels.

Mammalian target of rapamycin protein (mTOR) is a key player in the regulation of energy homeostasis, acting to reduce cell growth and differentiation in undernutrition. A link between mTOR and kisspeptin was suggested when antagonism of mTOR by rapamycin led to reduced kisspeptin expression in the ARC and reduced plasma LH levels.[36]

Starvation as well as feeding a high-fat diet (HFD) impair testosterone secretion. Fasting for 18 to 24 hours in monkeys is associated with lower and delayed testosterone response to intravenous kisspeptin injection.[37] In a study of the effects of an HFD in sexually immature and sexually mature male rats, the feeding of HFD was associated with increased body weight, impaired glucose tolerance, reduced testosterone levels, decreased hypothalamic kisspeptin receptor expression, and decreased LH responsiveness to kisspeptin.[38]

Regulation of Gonadotropins by Stress

Stress is a profound inhibitor of reproductive function in mammals, causing suppression of hypothalamic GnRH secretion and hypogonadotropic hypogonadism. Increased signaling of the hypothalamic neuropeptide corticotrophin-releasing factor (CRF) inhibits GnRH secretion and downregulates the expression of kisspeptin and its receptor in the ARC and medial POA (mPOA) of mice in response to central injection of CRF.[39] Reduced kisspeptin and kisspeptin receptor expression is also observed in response to other stressors including restraint, insulin-induced hypoglycemia, and injection of lipopolysaccharide (LPS).

The amygdala is a component of the limbic system implicated to have inhibitory effects on GnRH secretion. Manganese-enhanced magnetic resonance imaging (MRI) has shown that peripheral kisspeptin administration markedly reduces signal intensity in the amygdala in rodents. Furthermore, direct intra-medial amygdala (MeA) administration of kisspeptin increases LH secretion, whereas intra-MeA kisspeptin antagonist decreases LH secretion and LH pulse frequency.[40]

The bacterial endotoxin LPS reduces GnRH secretion in several mammalian species. Neonatal exposure to LPS causes delayed puberty and decreased kisspeptin mRNA expression in the mPOA of female rats. Furthermore, intraperitoneal administration of high-dose LPS in both ovariectomized and intact female rats reduces plasma LH levels and hypothalamic mRNA expression levels of kisspeptin and GnRH levels.[41]

Seasonal Regulation of Gonadotropin Secretion

Some animals use seasonal patterns of reproductive activity to maximize the survival of their offspring. During seasons of reproductive nonactivity, GnRH and gonadotropin secretion become quiescent in seasonal breeders. Recent evidence highlights the importance of the hypothalamic neuropeptide kisspeptin in mediating the seasonal activation of GnRH secretion. Increased hypothalamic kisspeptin expression has been reported in Syrian hamsters during long-day conditions, associated with increased sexual activity.[42] Furthermore, administration of kisspeptin-10 to Syrian hamsters under photoinhibitory conditions restored testicular, and therefore reproductive, activity.[43] Sheep are also known to be seasonal breeders, with increased reproductive activity during periods with short photoperiods to allow lambing in Spring. Increased ARC kisspeptin expression is observed in ewes during short photoperiods conditions. Conversely, during the long-day periods, kisspeptin expression in the ARC of ewes is reduced. Furthermore, kisspeptin administration in seasonally acyclic ewes (i.e., during a season of reproductive nonactivity) induces ovulation.[44] Kisspeptin receptor expression also varies seasonally. GnRH (and LH) responses to exogenous kisspeptin are greater in anestrus ewes than in seasonally active ewes during the luteal phase. In addition, kisspeptin receptor expression on GnRH neurons was greater during the nonbreeding season than during the breeding season. A recent study examined the expression of kisspeptin, NKB and DYN (which are coexpressed within hypothalamic KNDy neurons), in Syrian hamsters. They observed that all three neuropeptides were downregulated in the ARC under a short photoperiod.[45] The kisspeptin immunoreactivity is increased in the AVPV in Turkish hamsters exposed to long photoperiod conditions compared to hamsters exposed to short photoperiods as well as pinealectomized hamsters exposed to long photoperiods, suggesting a close relationship of pineal secretion of melatonin in the regulation of seasonal reproduction.[46]

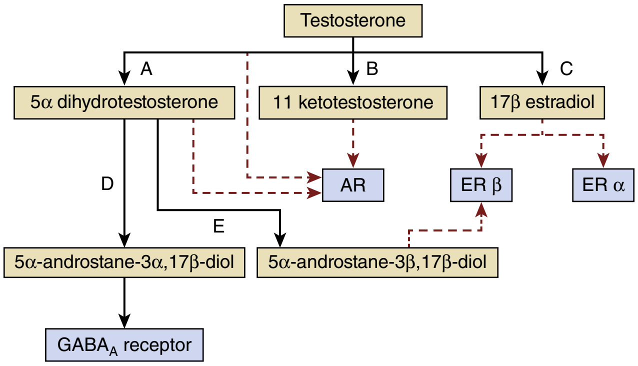

Figure 105.4 Testosterone can activate multiple signaling pathways through its conversion to other active metabolites. Testosterone exerts its biologic effects directly by itself or indirectly through its conversion to a number of metabolites: 5α dihydrotestosterone (DHT) a ligand for the androgen receptor, estradiol 17β a ligand for the estrogen receptor, 5α-androstane-3α,17β-diol, a modulator of gamma-aminobutyric acid (GABA$_A$) receptors[14] and 5α-androstan-3β,17β-diol a ligand for Erβ. The steroidal ligands are shown in *beige boxes* and the cognate receptors in *blue boxes*. A, SRD5A2 and 1; B, CYP11B2; C, CYP19A1; D, 3α-hydroxysteroid dehydrogenase; E, 3β-hydroxysteroid dehydrogenase.

KEY POINTS

- Increased levels of hypothalamic kisspeptin signaling trigger seasonal, reproductive activity in hamsters and sheep.
- Sepsis, hypoglycemia, and other experimental models of physiological stress suppress hypothalamic kisspeptin signaling.
- Starvation induces hypogonadotropic hypogonadism by suppressing hypothalamic kisspeptin signaling.

ANDROGEN PHYSIOLOGY

Testosterone is an important regulator of the masculinization of the structures that develop from the Wolffian ducts and the urogenital sinus; the development and maintenance of secondary sex characteristics; spermatogenesis; muscle and bone mass; hematopoiesis; metabolism; and many reproductive and nonreproductive behaviors. Testosterone exerts its biologic effects either directly through genomic and nongenomic mechanisms or indirectly through its conversion to one of its metabolites: 5α-dihydrotestosterone (DHT) a ligand for the AR, estradiol 17β a ligand for the ER, 5α-androstane-3α,17β-diol, a modulator of GABA$_A$ receptors[14] and 5α-androstan-3β,17β-diol, a ligand for ERβ (Fig. 105.4).[47–52] Thus, testosterone may expose different tissues to several biologically active metabolites that mediate the observed responses through multiple signaling pathways.

The Role of Aromatization in Mediating the Biologic Effects of Testosterone

Important insights into the role of estradiol in mediating testosterone's physiologic effects have emerged from studies of mice with genetic disruption of the CYP19A1 (aromatase enzyme), ERα, and ERβ genes, and human studies in which the conversion of exogenous testosterone was blocked by the administration of an aromatase inhibitor.[49,53–60] The effects of testosterone on bone resorption, epiphyseal closure, high-density lipoprotein (HDL) cholesterol, atherosclerosis progression, sexual desire, and fat mass require its conversion by the product of the CYP19A1 gene (aromatase) to estradiol 17β.[47,49,53,54] Mice with genetic disruption of the P450-linked CYP19 aromatase gene and humans with CYP19A1 mutations have increased fat mass and reduced muscle

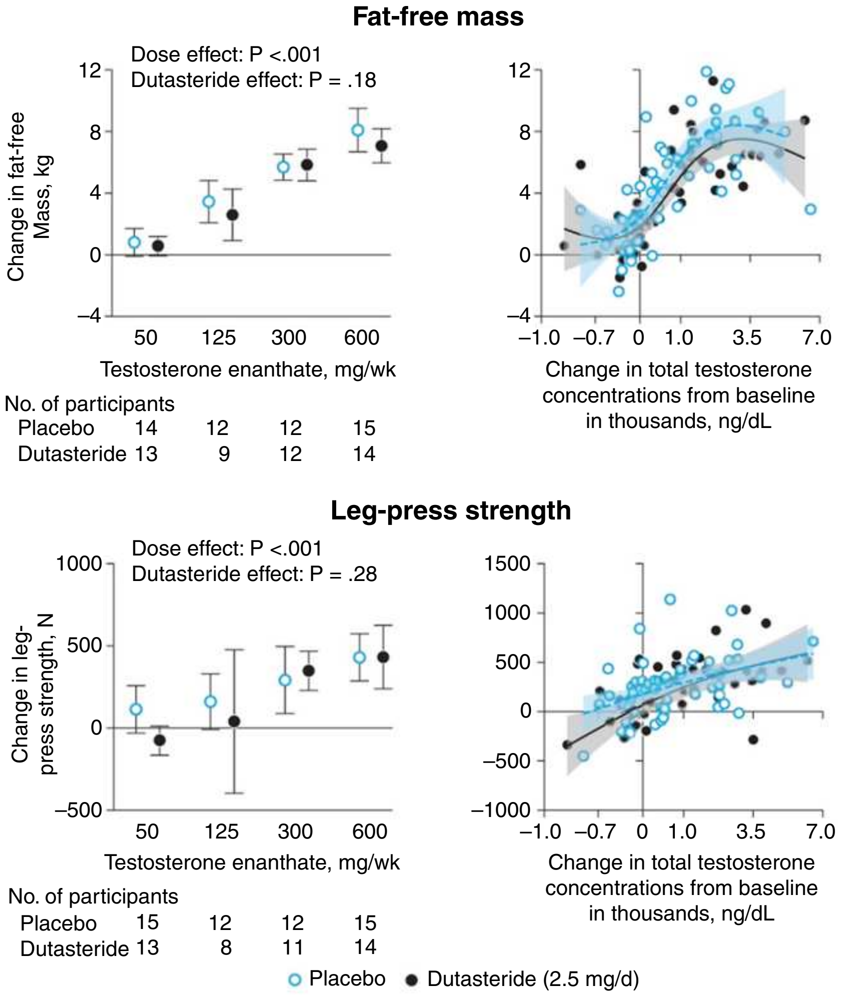

Figure 105.5 The role of 5-alpha-dihydrotestosterone in mediating testosterone's effects on skeletal muscle mass and strength in healthy young men. In this randomized trial, healthy young men were administered a long-acting gonadotrophin-releasing hormone (GnRH) agonist to suppress endogenous testosterone and randomized to either placebo or dutasteride (dual inhibitor of steroid 5α-reductase types 1 and 2) daily, plus 50-, 125-, 300-, or 600-mg testosterone enanthate weekly for 20 weeks. Changes in fat-free mass *(upper panel)* and leg-press strength *(lower panel)* were related to testosterone dose but did not differ between placebo and dutasteride groups. The relationship between change in total testosterone levels and change in fat-free mass and leg-press strength *(right panels)* did not differ between men assigned to placebo or dutasteride arms. (Reproduced with permission from Bhasin S, Travison TG, Storer TW, et al. Effect of testosterone supplementation with and without a dual 5alpha-reductase inhibitor on fat-free mass in men with suppressed testosterone production: a randomized controlled trial. *JAMA*. 2012;307(9):931–939.)

mass and exhibit insulin resistance,[53,61] suggesting that aromatization of testosterone to estradiol is important in mediating androgen effects on body composition. Testosterone's effects on lean mass, muscle size, and strength are not attenuated when its conversion to estradiol is blocked by the administration of an aromatase inhibitor.[49] However, testosterone's effects on fat mass, osteoclastic bone resorption as well as osteoblastic bone formation, and sexual desire are mediated by estradiol.[49] Mendelian randomization studies have revealed a stronger association of polymorphisms in the aromatase gene and genetically determined estradiol levels with bone mineral density and bone fracture risk than with testosterone levels.[62,63]

The Role of the Steroid 5α-Reductase System in Mediating the Biologic Effects of Testosterone

The conversion of testosterone to DHT by a family of steroid 5α-reductase enzymes (SRD5A1 and SRD5A2) is obligatory for mediating its effects on the differentiation of the urogenital sinus and the genital tubercle.[64] Testosterone's conversion to DHT also is believed to mediate its effects on hair growth, scalp hair loss, prostate growth, and acne. Men with benign prostatic hypertrophy who are treated with a steroid 5α-reductase inhibitor do not experience muscle or bone loss.[65] Similarly, individuals with congenital steroid 5α-reductase deficiency have normal muscle development at puberty.[66] In healthy young men in whom endogenous testosterone production was suppressed by the administration of a long-acting GnRH agonist, the anabolic effects of graded doses of testosterone on muscle mass and muscle strength, hemoglobin and hematocrit; bone markers; and sexual function were not blocked by dutasteride, a potent dual inhibitor of steroid 5α-reductase type 1 and 2 enzymes.[48] (Fig. 105.5) Thus, testosterone's conversion to DHT is not required for mediating its effects on muscle mass and strength, or bone mineral density, plasma lipids, and erythropoiesis.

Activation of Other Signaling Pathways by Metabolites of Testosterone

In specific brain regions, testosterone is converted locally to DHT, which is further converted in some cell types to 5α-androstane-3α,17β-diol, a modulator of GABA_A receptors and 5α-androstan-3β,17β-diol, a ligand for ERβ.[50–52,67–69] These metabolites play an important role in mediating testosterone's effects on mood and behavior and Alzheimer's disease neuropathology[50,51] (Fig. 105.4).

KEY POINTS

- Although testosterone is the predominant androgen in most mammalian species, it can also activate other signaling pathways through its conversion to its metabolites, such as 5α-dihydrotestosterone, a ligand for the androgen receptor; 17β estradiol, a ligand for the estrogen receptor; 5α-androstane-3α,17β-diol, a modulator of GABA_A receptors; and 5α-androstan-3β,17β-diol, a ligand for ERβ.
- The effects of testosterone on bone resorption, epiphyseal closure, high-density lipoprotein cholesterol, atherogenesis, sexual desire and some other behaviors, and fat mass, distribution, and metabolism require its conversion to 17β estradiol.
- The conversion of testosterone to 5α-DHT is required for the masculinization of the urogenital sinus and the genital tubercle but is not obligatory for mediating its effects on muscle mass and strength, hematopoiesis, and bone.

Biosynthesis of Testosterone and Other Androgens

More than 90% of circulating testosterone in men is derived from its biosynthesis in the Leydig cells that reside in the interstitial compartment of the testes; the remainder is derived from steroidogenic precursors in the adrenal gland. Cholesterol within the steroidogenic cells is derived mostly from three sources: its *de novo* synthesis in the endoplasmic reticulum; its mobilization from the plasma membrane; uptake of circulating cholesterol esters mediated by receptors found on the plasma membrane; and mobilization of cholesterol stored in lipid droplets.[70] In the mitochondria, the cholesterol available for steroidogenesis is bound to the cholesterol-binding domain of the translocator protein (TSPO)[71] Under the influence of LH in the testes and adrenocorticotrophic hormone in the adrenal gland, cholesterol bound to the cholesterol-binding domain of the TSPO is released and translocates to the inner mitochondrial membrane, where it is converted by the action of cholesterol side-chain cleavage enzyme (CYP11A1) and electron transferring proteins to pregnenolone.[72] The transport of intracellular cholesterol by the steroidogenic acute regulatory (StAR) protein from the outer mitochondrial membrane to the inner mitochondrial membrane is the rate-limiting process in testosterone biosynthesis. Mutations of the StAR protein are associated with congenital lipoid adrenal hyperplasia, a rare form of congenital adrenal hyperplasia (CAH) characterized by very low adrenal and gonadal steroids.[73]

The subsequent steps in testosterone biosynthesis take place in the endoplasmic reticulum. In the human testes, testosterone biosynthesis takes place predominantly via the delta-5 pathway, which involves the conversion of pregnanolone to 17α pregnanolone, by the 17α hydroxylase and the subsequent conversion of 17α pregnanolone to dehydroepiandrosterone (DHEA) by the 17,20-lyase reactions. The 17α hydroxylase and 17,20 lyase reactions are catalyzed by a single protein, CYP17A1; posttranslational modification (phosphorylation) of this enzyme and the presence of specific enzyme cofactors, such as cytochrome B5, confer 17,20-lyase activity selectively in the testis and zona reticularis of the adrenal gland. Abiraterone is a dual inhibitor of 17α hydroxylase and 17,20 lyase activities, which play an important role in local androgen synthesis in castration-resistant prostate cancers.

Although CYP17A1 is able to catalyze the conversion of progesterone to 17α-hydroxyprogesterone, most of δ4-androstenedione in humans is not derived from 17α-hydroxyprogesterone but rather from the conversion of 17α-hydroxy pregnenolone to DHEA in the δ5 pathway and further conversion of DHEA to δ4-androstenedione by the catalytic action of 3β-hydroxysteroid dehydrogenase.[74]

The Classical and the "Backdoor" Pathway for the Synthesis of DHT. Testosterone is typically converted in the testes and in some peripheral tissues to the more potent DHT by a family of steroid 5α-reductase enzymes.[64] At least two isoforms of steroid 5α-reductase, SRD5A1 and SRD5A2, have been described; the well-described kindreds with 5α-reductase deficiency have had mutations in SRD5A2, the predominant form in the prostate and the skin.[64] Finasteride predominantly inhibits SRD5A2, while dutasteride is a dual inhibitor of both SRD5A1 and SRD5A2.

DHT can also be derived through the backdoor pathway in which progesterone is converted by SRD5A1 to 5α-dihydroprogesterone, allopregnanolone, 17-hydroxy allopregnanolone, androsterone, androstanediol, and eventually to DHT. Recent reports of mutations in AKR1C2/4 genes in undervirilized 46, XY individuals suggest that the backdoor pathway for DHT formation, which was originally described in the tammar wallaby, is active in the human fetal testis.[75] The placental progesterone serves as a substrate for the synthesis of androsterone via the backdoor pathway in several nongenital tissues, which is then converted to DHT in the genital tubercle.[76]

The Biosynthesis of 11-Oxygenated Androgens. 11-Oxyandrogens are 19-carbon steroids that contain an oxygen atom on carbon 11 and have androgenic activity. 11β-hydroxysteroid dehydrogenase types 1 (CYP11B1) and 2 (CYP11B2) are expressed in the Leydig cells, the theca cells, and the *zona reticularis* of the adrenal gland[77–79]; testosterone as well as delta 4 androstenedione can serve as substrates for CYP11B1, resulting in the formation of 11β-hydroxytestosterone and 11β-hydroxyandrostenedione, respectively. CYP11B2 then converts 11β-hydroxytestosterone and 11β-hydroxyandrostenedione to 11-ketotestosterone and 11-ketoandrostenedione, respectively, mostly in peripheral tissues. Delta 4 androstenedione is the predominant substrate for CYP11B2 in the adrenal gland due to the high levels of delta 4 androstenedione produced in the zona reticularis although most of the 11-keto androgens are produced in the peripheral tissues.[77,79] 11-ketoandrostenedione can also be converted by AKR1C3 to 11-ketotestosterone. 11-Oxygenated steroids—11-ketotestosterone and 11-ketodihydrotestosterone—are potent androgens, with potencies equivalent to those of testosterone and dihydrotestosterone.[79] In fact, 11-ketotestosterone circulates in the plasma of men and women in appreciable concentrations (~20 to 30 ng/dL) without sexual dimorphism.[78] Growing evidence suggests that 11-oxygenated androgens may play an important role in several disorders of androgen excess, such as premature adrenarche, polycystic ovary syndrome, CAH, as well as in androgen-dependent cancers, such as castration-resistant prostate cancer.[79]

KEY POINTS

- The transport of intracellular cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane by the mediation of the StAR and translocator (TSPO) proteins is the rate-limiting step in testosterone biosynthesis.
- In adults, testosterone is converted in the testes and in some peripheral tissues to 5α-DHT by one of at least two isoforms of steroid 5α-reductase, SRD5A1 and SRD5A2; in the human fetus, 5α-DHT is derived mostly through the "backdoor pathway" in which progesterone is converted by SRD5A1 to 5α-dihydroprogesterone, allopregnanolone, 17-hydroxy allopregnanolone, androsterone, androstanediol, and eventually to DHT.
- 11-Oxygenated steroids—11-ketotestosterone and 11-ketodihydrotestosterone—potent androgens, are produced in appreciable amounts by the adrenal gland, testis, and some peripheral tissues by the action of CYP11B1 and CYP11B2.

TABLE 105.2 Structure Activity Relationship in Androgens

Structure Activity Relationship	Compounds	Chemical Structure
The basic structure of testosterone and the carbon numbering system	Testosterone	<Table Fig 105.2a>
17α-alkyl substitution retards presystemic first-pass metabolism	17α-Methyltestosterone	<Table Fig 105.2b>
Removal of 19 methyl group increases anabolic activity	19-Nortestosterone (nandrolone) series of compounds	<Table Fig 105.2c>
7α-Alkyl substitution increase anabolic activity and prevent its 5α reduction	7α-Methyl-19-nortestosterone	<Table Fig 105.2d>
Esterification of the 17β hydroxyl group renders the molecule more hydrophobic and extends the duration of action when injected into oil	Testosterone enanthate	<Table Fig 105.2e>
C2 carbon atom with an oxygen atom in 17α-alkylated AAS can improve metabolic stability	Oxandrolone	<Table Fig 105.2f>
Introduction of double bonds between the C9 and C10 positions and between the C11 and C12 positions can confer greatly increased potency	Trenbolone	<Table Fig 105.2g>

Structure Activity Relationship in Steroidal Androgens

Testosterone is a 19-carbon androgen with a cyclopentanophenanthrene ring structure that contains a 17-hydroxyl group, a 3-keto group, and a double bond between carbon 4 and 5 (Table 105.2).[80–82] Structural modifications of the testosterone molecule can modify its AR-binding affinity, AR stabilization, coactivator recruitment, nuclear translocation, DNA-binding affinity, presystemic metabolism, specificity as a substrate for the steroid 5α-reductase and the aromatase enzymes and its tissue specificity, and metabolic clearance.[81,82]

The addition of a methyl or an ethyl group to the 17α carbon position inhibits the presystemic metabolism of testosterone, extending its half-life and rendering it orally active; 17α-methyltestosterone is an example (Fig. 105.2).[80–82] However, orally administered 17α-alkylated androgens are potentially hepatotoxic and markedly suppress plasma HDL cholesterol and their use to treat hypogonadism is not recommended.

Removal of the methyl group in C19 position increases the anabolic activity; this modification has formed the basis of the 19-nortestosterone (nandrolone) series of compounds that were approved for the treatment of anemia and osteoporosis and are still widely used as anabolic drugs by recreational bodybuilders and athletes.[80–82]

Alkyl substitutions in the 7 position also increase the anabolic activity and reduce susceptibility for 5α reduction. Among the many 7α alkylated compounds that have been developed, 7α-methyl-19-nortestosterone (MENT) has undergone human trials.

The substitution of C2 with oxygen in oxandrolone increases the stability of the 3-keto group and its anabolic activity and prevents its aromatization. Oxandrolone also has a 17α-methyl group that renders it orally active. Because of its high anabolic activity relative to its androgenic activity, it is often used by female athletes.

In stanozolol, the 3,2-pyrazole group on the first cyclohexane ring enhances AR binding and the C17 methyl group makes it orally active. The 2-hydroxymethylene group in oxymetholone adds stability to the 3-keto group and increases its anabolic activity and the 17α methyl substitution prevents its presystemic metabolism and makes it orally active.

Orally administered testosterone is absorbed rapidly, but it undergoes rapid presystemic metabolism in the intestinal lumen and wall and in the liver. The esterification of the 17β-hydroxyl group with a carboxylic acid group (ester linkage) increases the hydrophobicity of the molecule. Testosterone enanthate, cypionate, and undecanoate are examples of testosterone esters that are currently used in clinical practice. The longer the side chain, the greater the hydrophobicity of the molecule; when injected intramuscularly in oil, these hydrophobic esters are released slowly from the oil depot in the muscle into the aqueous plasma thereby increasing its duration of action.[83] The half-life of testosterone esters in the human plasma is short; their long duration of action is largely due to their slow release from the oil depot in the muscle rather than from slower hydrolysis in plasma.

The Regulation of Testosterone Production by LH

Testosterone production and secretion by the Leydig cells are regulated by LH through a feedback and feedforward system. As discussed earlier, the negative feedback effects of testosterone, estradiol, and progesterone are mediated through KNDy neurons in the POA by inhibition of kisspeptin release[84]; testosterone also exerts direct stimulatory effect on pituitary FSH secretion.[26]

LH binds to a specific rhodopsin-like G-protein-coupled LH/chorionic gonadotropin receptor (LH/CGR), induces a conformational change in the receptor, the dissociation and release of the G-protein stimulatory Gs alpha subunit, activation of the adenylyl cyclase, and a rapid increase in the cyclic adenosine monophosphate (cAMP) and intracellular calcium.[85,86] The second messenger cAMP activates protein kinase A and phosphorylation of the transcription factor cAMP response element-binding (CREB) protein that binds target DNA sequences and regulates the transcription of genes encoding the steroidogenic enzymes in a cell type-specific manner. The activation of pERK1/2 is required for the steroidogenic response to LH in Leydig cells.[86] The signaling cascade is triggered by the Gaq protein activating phospholipase C, with subsequent cleavage of phosphatidylinositol bisphosphate to diacyl glycerol and inositol trisphosphate that binds calcium channels in the endoplasmic reticulum, resulting in calcium release.[85–87] LH receptor mutations cause Leydig cell hypoplasia or agenesis, underscoring the importance of this pathway for Leydig cell development and function.[88]

KEY POINTS

- LH stimulates testosterone production by binding to a specific G-protein–coupled LH/chorionic gonadotropin receptor (LH/CGR) to activate adenylyl cyclase, increase cAMP, and activate protein kinase A.
- LH also activates phospholipase C resulting in calcium release. The activation of pERK1/2 also plays an important role in the steroidogenic response to LH in Leydig cells.

Transport and Bioavailability

The circulating sex hormones—testosterone, dihydrotestosterone, and estradiol—are transported in human plasma bound predominantly to human serum albumin and sex hormone-binding globulin (SHBG),

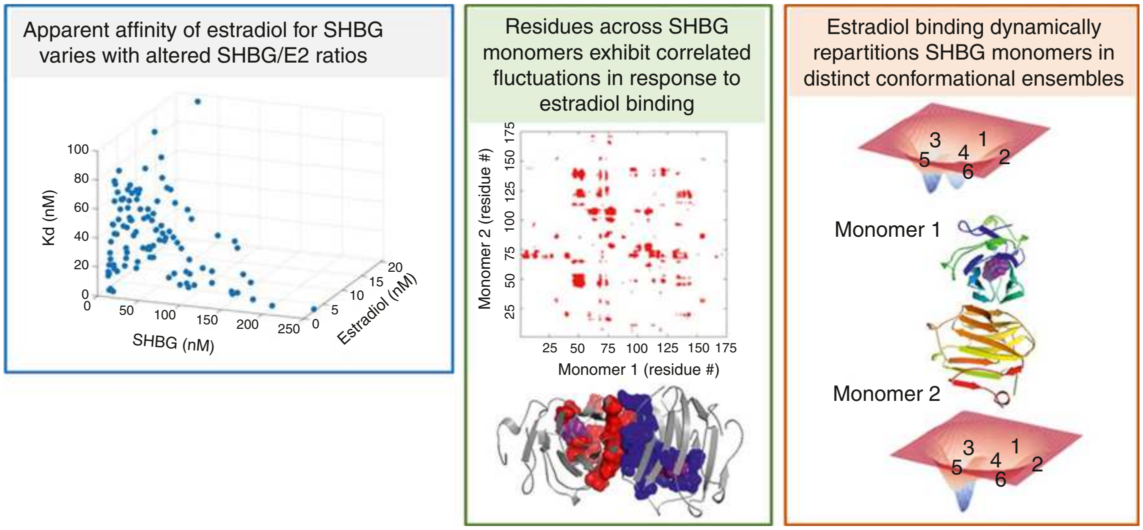

Figure 105.6 *Left,* The apparent binding affinity of estradiol varies as the concentrations of estradiol and sex hormone–binding globulin (SHBG) are varied. *Middle,* Dynamic cross-correlation matrices for SHBG dimer. The quadrants depicting the intermonomer correlation show changes in coordinated movement of the residues in the two monomers. *Red color* intensity stands for strength of residue correlation. Collectively, these data show that allosteric coupling in binding estradiol is manifested through coordinate, dynamic rearrangement in SHBG monomers. *Right,* Allosteric modulation of relative probabilities of the population of conformational clusters in response to estradiol binding (the five major conformational clusters are depicted). Contrary to the prevailing linear model, two unliganded SHBG monomers populate distinct conformational states. The populations of the liganded and unliganded monomers redistribute upon estradiol binding to either of the monomers. (Reproduced with permission from Jasuja R, Spencer D, Jayaraj A, et al. Estradiol induces allosteric coupling and partitioning of sex-hormone-binding globulin monomers among conformational states. *iScience.* 2021;24(6):102414.)

and to a lesser degree to α1-acid glycoprotein (orosomucoid), and cortisol-binding globulin (CBG),[89] and in rodents that lack SHBG, possibly also to lipoproteins. These binding proteins regulate the distribution, metabolism, elimination, and biologic activity of testosterone, dihydrotestosterone, and estradiol.[89]

Sex Hormone-Binding Globulin. SHBG is a homodimeric glycoprotein with a molecular mass of approximately 90 kDa that is produced in the liver of higher mammals but not in rodents and can bind to all three major sex steroid hormones.[90] In men, approximately 44% of testosterone is bound to SHBG, while in women, a greater fraction—approximately 66%—is bound to SHBG.[91] For a number of years, it was believed that testosterone's binding to each of the two SHBG monomers was linear and equivalent and conformed to a 1:1 stoichiometry with a binding affinity of ~1 nM.[92–94] Recent studies using modern biophysical techniques have shown that the binding of testosterone to SHBG is a nonlinear dynamic process such that the binding affinity and conformational states of the two monomers in unliganded as well as liganded states are not equivalent (Fig. 105.6).[95]

Some studies have suggested that extracellular SHBG may bind to a membrane receptor that is coupled to an adenylate cyclase-mediated signaling cascade or may even activate AR signaling in the prostate.[96,97] It has also been suggested that SHBG may transport testosterone intracellularly through a megalin-mediated endocytic process.[98] However, further independent validation of these findings has not emerged.

Does SHBG Exert Biologic Effects Other Than as a Transport Protein?. Whether SHBG exerts biologic effects in addition to serving as a transport protein for sex hormones is unknown. Serum SHBG levels and SHBG polymorphisms that are associated with higher SHBG levels are independent predictors of the risk of type 2 diabetes, metabolic syndrome, and bone fractures, even after adjusting for testosterone concentrations.[99–101]

Human Serum Albumin. Human serum albumin comprises three homologous domains; domains II and III contain binding pockets that are formed mostly of hydrophobic and positively charged residues in which a variety of compounds bind.[102,103] Human serum albumin possesses multiple binding sites for several biomolecules, including nonesterified fatty acids and many commonly used drugs. However, it has been generally believed that testosterone binds to human serum albumin at a single site on domain IIA with low-to-moderate affinity ($K_a \approx 2.0 - 4.1 \times 10^4\ M^{-1}$ at 37°C) and 1:1 stoichiometry.[92–94,104] Studies using two-dimensional nuclear magnetic resonance (2D NMR), fluorescence spectroscopy, bis-ANS partitioning, and molecular modeling have provided evidence of multiple, allosterically coupled binding sites for testosterone on human serum albumin (Fig. 105.7).[105] Testosterone shares these binding sites on human serum albumin with free fatty acids and many commonly used drugs, such as ibuprofen and coumadin, which could displace testosterone from human serum albumin under various physiological states or disease conditions, affecting its bioavailability.[105]

The Significance of the Unbound Fraction: The Free Hormone Hypothesis. The free hormone hypothesis postulates that only the unbound or free testosterone fraction is able to diffuse into the target cell and exert its biologic effect.[106] Consistent with the free hormone hypothesis, the Endocrine Society Guideline suggests measuring free testosterone concentrations in men with conditions in which alterations in binding protein concentrations are suspected.[107] The validity of the free hormone hypothesis has been debated extensively. In an effort to test the free hormone hypothesis, Laurent et al.[108] generated transgenic mice expressing a human SHBG transgene. The SHBG transgenic mice exhibited higher total testosterone and estradiol

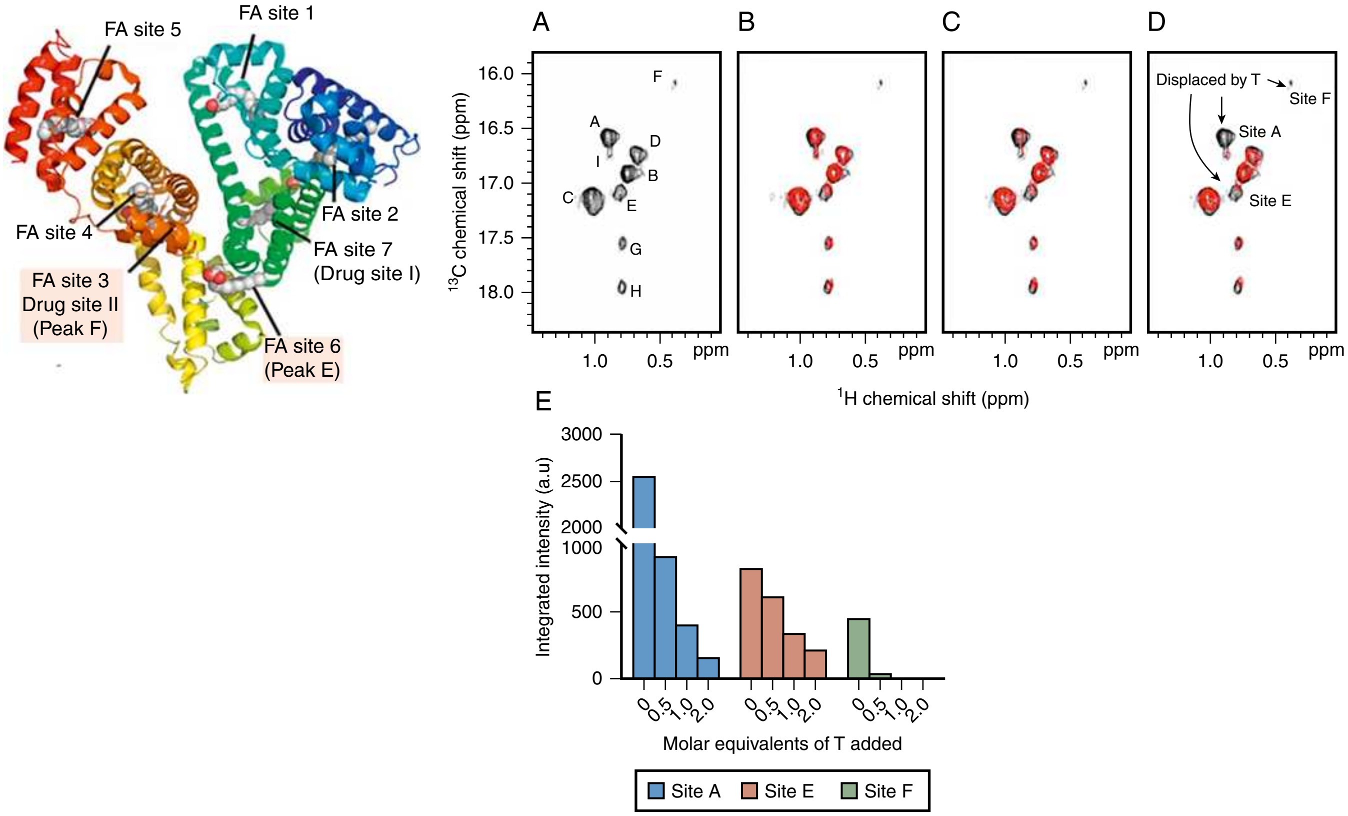

Figure 105.7 The crystal structure of human serum albumin (HSA) and testosterone's binding to multiple fatty acid-binding sites on HAS. *Left,* HSA crystal structure showing the fatty acid–binding sites that have been resolved in the crystal structure. *Right,* **A**, Nine resonances were observed from ^{13}C-OA binding to HSA (2 mM OA, 0.5 mM HSA) bound sites. **B-D**, Decrease in nuclear magnetic resonance signal from binding pockets corresponding to peaks A, E, and F as the OA is displaced by increasing testosterone concentrations. Red resonances in **B**, **C**, and **D** are from sites that are occupied by OA in the presence of testosterone. **A**, The spectra obtained from 4:1 ratio of OA:HSA in absence of testosterone; **B**, in the presence of 0.5 molar equivalents of testosterone; **C**, upon addition of 1 molar equivalent of testosterone; and **D**, in the presence of 2 molar equivalents of testosterone. **E**, The four spectra were analyzed using CCPNMR software to determine the peak intensity at corresponding concentrations of testosterone. Allosterically coupled multisite binding of testosterone to human serum albumin. *Endocrinology*. 2021;162(2).)

concentrations compared to wild-type controls but had normal free testosterone concentrations.[108] The SHBG transgenic mice had higher LH concentrations and lower prostate and seminal vesicle volumes than wild-type controls. When wild-type mice and SHBG transgenic mice were castrated and given equivalent doses of testosterone implants, free testosterone levels, as well as the wet weights of androgen-sensitive organs (seminal vesicles and levator ani/bulbocavernosus), were significantly lower in SHBG transgenic mice than in wild-type mice.[108] These data support the notion that SHBG regulates the bioavailability of testosterone in androgen-responsive tissues.

Genetic polymorphisms in the human *SHBG* gene have been associated with SHBG levels and binding affinity, as well as with total testosterone levels.[109,110] Patients with polymorphisms associated with undetectable SHBG concentrations offer a unique opportunity to evaluate the free hormone hypothesis. Vos et al.[111] described a brother and sister who were homozygous for a missense mutation within the *SHBG* gene (p.G224R SHBG) and had undetectable SHBG in their plasma. Both affected siblings had normal gonadal development and function suggesting a limited role for SHBG in sexual maturation and physiology. The male subject with the undetectable SHBG had very low total testosterone but normal free testosterone level, normal LH and FSH, and normal pubertal development and spermatogenesis. However, the male subject reported symptoms similar to those reported by men with testosterone deficiency, such as low libido, decreased spontaneous morning erections, fatigue, muscle weakness, depressed mood, and sleep disturbance. The women with undetectable SHBG levels have been reported to exhibit hyperandrogenism, hirsutism, and amenorrhea.[112]

In an analysis of the European male Aging Study,[113] low free testosterone was more strongly associated with clinical features of testosterone deficiency than total testosterone. In another analysis of men who were evaluated for hypogonadism,[114] 62% of patients with low total testosterone had a normal calculated free testosterone concentration. Thus, accurate measurement of serum free testosterone concentration is necessary for most men to confirm the diagnosis of testosterone deficiency.[114]

KEY POINTS

- Binding of circulating sex hormones to SHBG, human serum albumin, CBG, and orosomucoid regulates their distribution, metabolism, elimination, and biologic activity.
- Testosterone's binding to SHBG dimer is a dynamic, nonlinear process that involves allosteric interactions between the two SHBG monomers such that the binding affinities and conformation of the two monomers in the liganded or unbound state are not equivalent.
- Testosterone binds to multiple binding sites of human serum albumin that also bind fatty acids and commonly used drugs.

Testosterone Metabolism

As discussed earlier, testosterone is converted to DHT and estradiol in many peripheral tissues. In addition, testosterone is converted mostly in the liver to various inactive metabolites via enzymatic oxidation, reduction, and hydroxylation of the A, B, C, and D rings and excreted in the urine either as a glucuronide or as a sulfate; only 2% is excreted as unconjugated testosterone.[115,116] The major urinary metabolites of testosterone, androsterone, and etiocholanolone are formed by the catalytic action of the enzyme 17β-hydroxydehydrogenase and are excreted as 17-ketosteroids. These inactive metabolites are conjugated in the liver and kidney with either glucuronic acid through the catalytic actions of UDP-glucuronosyltransferase enzymes or sulfotransferase.[115,116] Some synthetic androgens such as oxandrolone are excreted mostly in the unconjugated form.[115] Detection of androgens or their metabolites in the urine is the basis of current drug testing.

Mechanisms of Testosterone's Action

Testosterone and the Androgen Receptor. Many physiologic actions of testosterone and 5α-DHT, including its effects on sexual differentiation of urogenital structures, spermatogenesis, muscle and bone, immune system, and erythropoiesis, are mediated through the classical AR; the nongenomic actions of testosterone are less well understood. The AR, a member of the nuclear receptor superfamily, is a 919-aa, 110-kDa, ligand-inducible transcription factor that regulates the transcription of androgen-responsive genes and mediates many of the biologic effects of testosterone and other androgens.[117,118]

AR possesses six characteristic structural domains A-B, C, D, E, and F.[117–119] The domain A/B includes activation function 1 (AF-1) (residues 101 to 370) that is required for full ligand-activated transcriptional activity; AF-5 (residues 360 to 485) that is responsible for its constitutive activity without ligand binding; and a dimerization surface involving residues 1 to 36 containing the FxxLF motif and residues 370 to 394 that interact with the ligand-binding domain (LBD).[119–121] The AF-1 transactivation domain, located in the N-terminal region, binds different coregulator proteins that enable liganded AR to subserve diverse physiologic functions.[119–121] Domain C serves as the DNA-binding domain (DBD). The DBD is organized in two zinc finger binding motifs that direct binding as homodimers. The target androgen response element (ARE) typically consists of one or two DNA consensus sequences that are arranged as inverted repeats—the distance between these repeats determines the binding specificity. The DBD (545 to 675 aa) is well conserved and binds with high affinity to the AREs and other transcription factors bound to the AREs.[119–121] Domain D serves as the hinge region that separates the DBD from the LBD, provides flexibility to the AR so it can assume different conformations depending upon the bound ligand, and contains a nuclear localization signal.[122] Domain E contains the LBD, the AF-2, and a nuclear export signal.[118,121,122] The highly conserved LBD in the C terminus (690 to 919 aa) confers ligand specificity for androgens and also contains domains that can mediate the binding of heat shock proteins, receptor dimerization, and nuclear localization.[122] The N-terminal region of domain E contains another activation domain, AF-2, that is responsible for agonist-induced activity (see later).[122] The N-terminal region (1 to 514 aa) is not well conserved, has been difficult to crystallize, and contains several unstructured domains.

AR contains two AF regions located in the N-terminal (AF-1) and the C-terminal halves of the protein (AF-2) that regulate the interactions between N-terminal and C-terminal domains of the AR as well as the recruitment of coactivator and corepressor proteins in a ligand-specific manner.[123–125] The AR AF-2 plays two functional roles: (1) in the unliganded state, it associates with FxxLF (residues 23 to 27) and WxxLF (residues 433 to 437) motifs observed in the N-terminal domain (NTD) to keep the AR in an inactive conformation and (2) upon ligand binding, the liganded AR recruits coregulators that possess LxxLL and FxxLF motifs, including p160 family, ARA55, ARA55, ARA70, NCoRs, and steroid receptor coactivators (SRCs).[125] Selective recruitment of the coregulators elicits ligand-specific, tissue-specific, AR-mediated transcriptional activity.[125] Two transcription activation units, Tau-1 and Tau-5, within the AF-1 are obligatory and sufficient for the activity of the isolated AR-NTD and the full-length AR[126]; mutations in Tau-1/Tau-5 render the AR protein inactive.[126]

Unliganded AR is located primarily in the cytoplasm; in response to ligand binding, AR undergoes distinct conformational changes, leading to dissociation of heat shock proteins, recruitment of coregulators and chaperone proteins, translocation to the nucleus, dimerization, chromatin remodeling, DNA binding, and regulation of transcriptional activity of AR-responsive genes.[127,128] The various domains of AR act in concert to conformationally gate the transcriptional response to agonist or antagonist binding.[128] Collectively, the transcriptional activity of AR is regulated by a spatiotemporal interplay between domains and motifs. Ligand binding and coregulator protein-induced conformational dynamics enable the domains to exhibit multiple functional roles.

The crystal structure of C-terminal LBD of the nuclear hormone superfamily displays highly conserved arrangement of 12 α helices.[129–131] While AR contains 11 helices, they are still numbered from 1 to 12 (helix 2 is skipped) to reflect the shared functional organization with helix 12 acting as a flexible, conformational gate.[121,129–131] Ligand binding is associated with significant rearrangement in the immediate vicinity of the residues in the binding pocket as well as in distant residues in other domains. The DBD binds with high affinity to the AREs to induce transcriptional activity. While AR shares affinity for consensus sequence 5’-TGTTCT-3’ with other nuclear receptors, such as GR and PR, it also has selective ARE, including PB-ARE2 and Slp-HRE2.[121,131] These interactions of the DBD and ARE regulate the recruitment of enhancers/promoters to the macromolecular transcriptional assembly.[131–133] The crystal structures of liganded LBD and DBD have been described, but no crystallographic or solution NMR structures have been solved for the NTD or its fragments. It is conceivable that the conformational flexibility of NTD enables intra- and interdomain steric interactions.

Polymorphisms in Trinucleotide Repeats in the Androgen Receptor. The human AR gene contains two polymorphic trinucleotide repeats of CAG and GGC, which code for polyglutamine and polyglycine tracts in exon 1 of AR.[134] The length of the polyglutamine tracts has been associated negatively with the transcriptional activity of AR. Very long polyglutamine tracts have been associated with a rare inherited X-linked motor neuron disorder, the Spinal and Bulbar Muscular Atrophy, or Kennedy's disease.[135] The AR protein with very long polyglutamine tracts forms aggregates that are toxic to the neuronal cells.[135]

Mechanisms of Testosterone's Effects on the Skeletal Muscle. Testosterone administration increases skeletal muscle mass, maximal voluntary strength, and muscle power. Testosterone-induced increase in skeletal muscle mass is related to the administered dose and circulating testosterone concentration[136,137] and is associated with the hypertrophy of both type 1 and type 2 muscle fibers.[138–140] Testosterone does not increase the numbers or relative proportion of type 1 or type 2 muscle fibers. Testosterone-induced muscle fiber hypertrophy is associated with dose-dependent increases in myonuclear number and satellite cell number.[140] Testosterone promotes the differentiation of mesenchymal multipotent muscle progenitor cells into the myogenic lineage and inhibits the differentiation of these precursor cells into the adipogenic lineage.[141,142] Testosterone promotes the formation of myosin heavy chain II positive myotubes and upregulates markers of myogenic differentiation, such as MyoD and myosin heavy chain.[142] Testosterone and DHT inhibit adipogenic differentiation and downregulate markers of adipogenic differentiation, such as peroxisome proliferator-activated receptor gamma (PPARγ) and C/EBP∝.[142,143]

Testosterone's effects on myogenic differentiation are mediated largely through its binding to the classical AR,[142] which induces a conformational change in the AR, promoting its association with its coactivator, β-catenin, causing the complex to translocate into the nucleus. The AR-β-catenin complex associates with T cell factor 4 (TCF-4) and activates a number of Wnt target genes,[143,144] including follistatin (Fig. 105.8). Follistatin cross-communicates the signal from the AR-β-catenin pathway to the transforming growth factor (TGF)-β signaling pathway, blocking signaling through the TGF-β/Smad 2/3.[144] Follistatin plays an essential role in mediating the effects of testosterone on myogenic differentiation.[143,144]

Testosterone regulates polyamine biosynthesis in multiple androgen-responsive tissues, including the muscle, prostate, and kidney.[145] Testosterone depletion downregulates ornithine decarboxylase 1 (ODC1) enzyme, the rate-limiting step in the polyamine biosynthesis, and testosterone supplementation of orchiectomized mice upregulates ODC1[145,146] in the prostate as well as the muscle. Polyamine availability in the prostate is constrained because polyamines are being continually acetylated and secreted by the prostate. The administration of ODC1 inhibitor, α-difluoromethylornithine, to mice is associated with reduced prostate mass. In orchidectomized mice, testosterone supplementation restores prostate as well as *levator ani* muscle mass but concurrent administration of ODC1 inhibitor blocks testosterone's restorative effects on prostate mass but not on the *levator ani* mass, indicating that ODC1 plays an important role in mediating the effects of testosterone on the prostate.[145] Therefore, combined administration of testosterone plus ODC1 inhibitor provides a novel approach for achieving selectivity of testosterone's anabolic effects on the muscle while sparing the prostate.[145]

Mechanisms of Testosterone's Effects on Hematopoiesis.

Testosterone treatment is associated with a dose-related increase in hemoglobin and red cell number.[147] Testosterone acts on hematopoietic progenitor cells to increase the numbers of cells in stages that bear the transcriptional bias of multipotent common myeloid progenitors as well as early erythroid progenitors through an AR-mediated mechanism (Fig. 105.9).[148] Additionally, testosterone stimulates erythropoietin production and prevents its compensatory suppression even in the face of elevated red blood cell (RBC) counts, as indicated by higher levels of erythropoietin for any level of hemoglobin in testosterone-treated men compared to their pretreatment baseline.[149] Consistent with this effect on multipotent hematopoietic progenitors in the bone marrow, testosterone also increases the numbers of circulating neutrophils, monocytes, and platelets—not just RBCs—all of which are derived from myeloid series progenitors.[148] Testosterone stimulates iron-dependent erythropoiesis by suppressive hepcidin.[150] Testosterone suppresses hepcidin transcription in the liver by blocking BMP-SMAD signaling, increases iron recycling and export from the spleen by increased expression of ferroportin in the spleen, and increases serum iron and the incorporation of transferrin-bound ^{58}Fe into the RBCs of testosterone-treated mice compared to controls.[150] Additionally, testosterone stimulates erythropoietin production

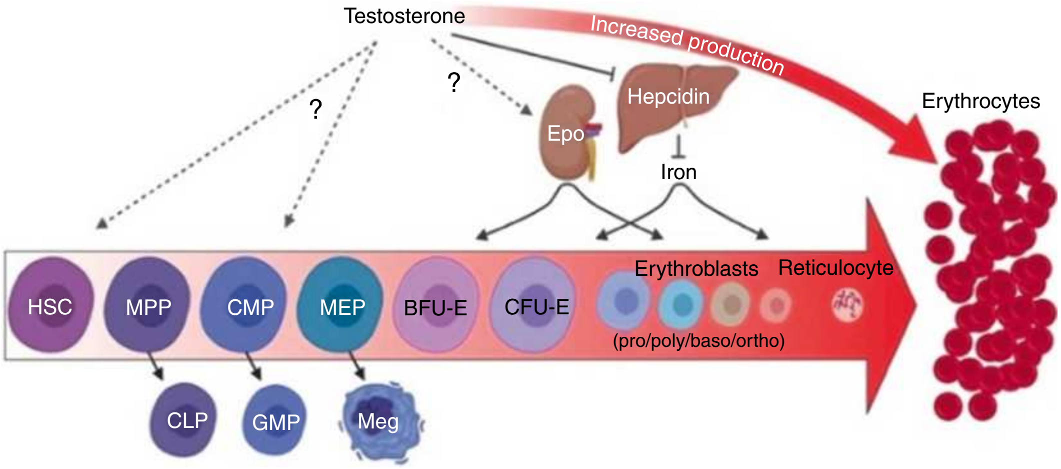

Figure 105.9 An integrated model of the mechanisms by which testosterone increases red cell counts. Testosterone increases the numbers of myeloid series progenitors from which red blood cells, neutrophils, monocytes, and platelets are derived. Testosterone increases iron availability by suppressing hepcidin in an iron-replete state. Iron is essential for mediating testosterone's effects on erythropoiesis. Testosterone also stimulates erythropoietin, which plays a permissive role in enabling the terminal differentiation of erythroid progenitors. *BFU-E,* erythroid burst forming units; *CFU-E,* erythroid colony forming units; *CLP,* common lymphoid progenitors; *CMP,* common myeloid progenitors; *Epo,* erythropoietin; *GMP,* granulocyte-macrophage progenitors; *HSC,* hematopoietic stem cells; *Meg,* megakaryocyte; *MEP,* megakaryocyte-erythrocyte progenitors; *MPP,* multipotential progenitors.

and prevents its compensatory suppression even in the face of elevated RBC counts, as indicated by higher levels of erythropoietin for any level of hemoglobin in testosterone-treated men compared to their pretreatment baseline, enabling the terminal differentiation of the increased numbers of erythroid progenitors.[149]

Nongenomic Effects of Testosterone. Some effects of testosterone are mediated through nongenomic mechanisms that are independent of the ligand-dependent transcriptional effects mediated by the classical AR. These nongenomic effects occur rapidly over short periods of time, do not require transcription or protein synthesis, and are not blocked by AR antagonists such as flutamide.[151] Among the most well-characterized nongenomic effects of testosterone is the relaxation of the vascular smooth muscle in the blood vessel walls that results in vasodilatation and increased blood flow.[151,152] The vasorelaxation induced by testosterone is associated with inactivation of the L-type voltage-operated Ca^{2+} channels and activation of K^+ channels especially the voltage-operated K^+ channels and the large conductance Ca+-activated K^+ channel (BK_{Ca}).[151,153] Testosterone also increases endothelium-derived nitric oxide by inducing endothelial nitric oxide synthase (eNOS) phosphorylation (Ser^{1177}) via PI3K, caveolin-1 and c-proto-oncogene tyrosine-protein kinase (Src)[154,155]; these actions are not associated with increased protein synthesis and are not blocked by classical AR antagonists. The nongenomic effects of androgens exhibit structural specificity; thus, 5β-dihydrotestosterone is a substantially more potent vasodilator than 5α-dihydrotestosterone,[151] but in contrast to 5α-dihydrotestosterone, the 5β isoform does not exert any appreciable AR-mediated androgenic effects. Androgens also exert similar nongenomic effects in inducing relaxation of smooth muscles in the bronchi, urinary bladder, gall bladder, and intestines.[151]

KEY POINTS

- Androgens exert their biologic effects through genomic and nongenomic mechanisms.
- In response to ligand binding, AR undergoes conformational changes, leading to dissociation of heat shock proteins, recruitment of coregulators and chaperone proteins, translocation to the nucleus, dimerization, chromatin remodeling, DNA binding, and regulation of transcriptional activity of AR-responsive genes.
- Ligand binding and coregulator protein-induced conformational dynamics enable the domains to exhibit multiple functional roles in a tissue-specific manner.

ESTROGEN PHYSIOLOGY

Endogenous Estrogens

Human ovaries and some peripheral tissues produce several estrogens—estradiol, estrone, estriol, and catechol estrogens (Fig. 105.10)—with varying estrogenic potency and cell type specificity; these estrogenic compounds are 18 carbon steroids that share common structural features, including an aromatic A ring, a phenolic hydroxyl group at C3, and a hydroxyl or a keto group at C17.

Estradiol is the principal estrogen secreted by the ovary in menstruating women although it is also produced by peripheral conversion from testosterone in the adipose tissue, breast, liver, muscle, bone, and in many brain regions.[156,157] Estradiol promotes the development and maintenance of female reproductive tissues such as the breast, vagina, and the uterus during puberty, adulthood, and pregnancy; in women of reproductive age, increasing estradiol concentrations during the menstrual cycle promote the maturation and release of the oocyte and the ripening of the endometrial lining to enable implantation of the fertilized egg. Additionally, estradiol regulates reproductive and nonreproductive behaviors; epiphyseal closure, osteoblastic bone formation as well as osteoclastic bone resorption; adipose tissue distribution and metabolism; and muscle, skin, and neuronal health.

Ovaries also secrete estrone, but a major fraction of circulating estrone is derived from aromatization of delta-4 androstenedione in the peripheral tissues.[156,157] In postmenopausal women, the circulating concentrations of estrone are substantially higher than those of estradiol.[158] Estrone has substantially lower potency than estradiol in activating signaling through ERα; however, it can be converted to estradiol by the catalytic action of 17β-hydroxysteroid dehydrogenase isoenzymes. *In vitro*, the various isoforms of 17β-hydroxysteroid dehydrogenase are typically bidirectional; however, *in vivo*, the reductases mainly use nicotinamide adenine dinucleotide phosphate (NADPH) to preferentially reduce estrone to estradiol. In humans, 17β-hydroxysteroid dehydrogenase type 1 is the principal isoenzyme involved in estradiol production from estrone in the ovaries as well as in peripheral tissues. Estrone is also the most abundant component of Premarin, a commercially available estrogen compound that contains 10 or more estrogenic compounds, of which estrone constitutes 50% to 60%.

Estriol is produced by peripheral metabolism of estradiol and estrone and represents the most abundant estrogen in the urine of menstruating as well as pregnant women. Estriol has very low activity on ERα, but it can be converted to estradiol through the action of 17β-hydroxysteroid dehydrogenase enzymes.

Catechol estrogens are estrogen metabolites that are synthesized in the brain, liver, and other tissues by the addition of a hydroxyl group at C2 or C4.[159,160] The cytochrome P450-dependent monooxygenases, encoded by CYP1A1 and CYP1A2 catalyze 2-hydroxylation of estrogens, and the protein product of CYP1B1 serve as an estrogen 4-hydroxylase.[159,160] Catechol estrogens typically have short half-lives *in vivo* and are postulated to serve as local signaling molecules. However, they can bind ER albeit with lower affinity than estradiol and exert both genomic and nongenomic effects in the target cells. Catechol estrogens are potent inhibitors of the inactivation of catecholamines by catecholamine methyltransferase (COMT). The 2-hydroxyl estradiol exerts antiangiogenic effects[159,161] and inhibits cell proliferation. In contrast, 4-hydroxy estradiol can be further metabolized to reactive catechol estrogen quinones that react with DNA to form mutagenic depurinating adducts that are potentially mutagenic and can promote the initiation of carcinogenesis.[161,162]

16α-Hydroxyestrone, a product of 16α-hydroxylation of estrone, promotes dysregulation of DNA synthesis and anchorage-independent growth in mouse mammary epithelial cells.[163] Circulating concentrations of 16α-hydroxyestrone have been associated with the risk of breast cancer induction.[164,165]

Regulation of Estradiol Production

The follicular cells in the preovulatory follicles produce estradiol prior to ovulation and the corpus luteum produces estradiol and progesterone after ovulation. With the ovulatory LH surge, granulosa cells undergo terminal differentiation into the large luteal cells of the corpus luteum that secrete progesterone. In the ovarian follicle, the production of 17β-estradiol by the granulosa cells is dependent upon LH-stimulated synthesis of androstenedione by the ovarian theca interna cells and the FSH-stimulated aromatization of C19 androgens by CYP19A1 in the granulosa cells.[166–168] The rate-limiting steps in estradiol production by the ovary are the cholesterol transport from the outer to the inner mitochondrial membrane by the StAR protein necessary for the side-chain cleavage of cholesterol to form pregnanolone in the theca-interstitial cells and the aromatization of C19 androgens in the granulosa cells.[166,167]

The LH binds to LH/CG receptor on the theca interna cells of the small follicles to stimulate the expression of steroidogenic enzymes—StAR protein, *CYP11A1* (cytochrome P450 side-chain cleavage enzyme), and *CYP17A1* (cytochrome P450 17α hydrolase)—that are essential for the production of androgens by theca-interstitial cells.[169–171] The stimulatory actions of LH on theca cell steroidogenesis are mediated largely through the activation of the cAMP/protein kinase A signaling pathway.[169–171] Protein kinase A activation also induces the phosphorylation of ERK1/2, inhibition of progesterone synthesis,[172] and stimulation of androgens synthesis by modulating the transcription of genes encoding steroidogenic enzymes. In granulosa cells, LH regulates the expression of multiple genes involved in progesterone synthesis, paracrine signaling, signal transduction, cytoskeletal regulation, and apoptosis.[173]

The rate-limiting step in the acute LH-induced upregulation of steroidogenesis in the theca interna cells is the transport of the cholesterol from the outer to the inner mitochondrial membrane.[174] In steroidogenic cells, the StAR protein interacts with a mitochondrial protein complex to facilitate cholesterol delivery to the inner mitochondrial membrane[174] where it is converted to pregnenolone by the action of cytochrome P450 cholesterol side-chain cleavage enzyme complex that includes cytochrome P450 cholesterol side-chain cleavage enzyme and cofactors, adrenodoxin and flavoprotein.[175] Severe disruption of steroidogenesis observed in preclinical models with genetic disruption of the StAR gene as well as in patients with congenital lipoid adrenal hyperplasia who have naturally occurring mutations of the StAR protein provides strong evidence for the critical role of StAR protein in steroidogenesis.[176] Pregnanolone is converted to androstenedione through the catalytic action of 17-hyroxylase/17,20-lyase enzyme, a product of the CYP17A1, and 3β-hydroxysteroid dehydrogenase enzyme, a product of the HSD3B2 gene.[177] Most of the androstenedione in humans is produced through the delta-5 pathway. Androstenedione, the most important product of the theca cells during the follicular phase of the menstrual cycle, is a weak androgen, but it serves a precursor for both estrone and testosterone in the ovaries and peripheral tissues, which are further converted to estradiol.

The aromatase enzyme encoded by the CYP19A1 gene catalyzes the conversion of theca-derived androstenedione to estradiol.[166,167,178] In granulosa cells from preovulatory follicles, FSH stimulates the synthesis of aromatase (CYP19A1) by inducing cAMP production and activating protein kinase A and certain MAP kinases.[178] The CYP19A1 gene contains a large regulatory region that contains many tissue-specific promoters that are regulated by a distinct set of regulatory sequences and transcription factors.[178,179] The expression of the human aromatase gene in various estrogen-producing tissues is regulated by the tissue-specific promoters upstream of alternative first exons, which encode the tissue-specific 5′-untranslated regions of the aromatase transcripts.[179] In the human ovary, aromatase transcripts contain 5′-untranslated sequences encoded by exon IIa, which lies 110 base pairs upstream of the translation start site.[179] Two orphan members of the Ftz-F1 subfamily of nuclear receptors—the liver receptor homolog-1 (LRH-1; NR5A2) and steroidogenic factor-1 (SF-1; NR5A1)—are expressed in the ovary and play an important role in regulating estradiol biosynthesis in the ovary.[180,181] Steroid biosynthesis in the ovary is enhanced by the transcription factors SF-1 and LRH-1 through the regulation of CYP19A1 and other steroidogenic enzymes StAR, CYP11A1, HSD3B2, and CYP17A1.[181–183] FSH also promotes the binding of SF-1 and LRH-1 to the promoter of the aromatase gene.[182,183]

In addition to the regulation of CYP19A1, FSH stimulates follicular growth and induces LH receptors in the granulosa cells of the preovulatory follicle. FSH receptor is expressed only in the granulosa cells of the ovary, in contrast to LHCG receptor, which is expressed in theca-interstitial cells and by granulosa cells of large preovulatory follicles.[184,185]

Estrogen Transport and Bioavailability

Most of the circulating estradiol is bound to SHBG and human serum albumin. Although sex steroid binding to human serum albumin has been generally described as a low-affinity binding, recent studies using 13C-oleic acid NMR have revealed the presence of multiple binding sites on human serum albumin that are allosterically coupled.[105] Recent studies of estradiol's binding to SHBG show that estradiol binding to SHBG is also a dynamic process in which each estradiol binding to each SHBG monomer influences residues in the ligand-binding pocket of both monomers and differentially alters the conformational and energy landscapes of both monomers[186] (Fig. 105.6). The SHBG monomers are not energetically or conformationally equivalent in an unliganded, singly bound, or fully bound state. Intermonomeric allostery could be nature's mechanism to extend the binding range of SHBG and regulate hormone bioavailability as estradiol concentrations vary widely during life.[186] Estradiol and testosterone are oriented differently in the ligand-binding pocket of SHBG. Naturally occurring SHBG variants differ in their relative affinities for estradiol and testosterone.[187] Ng et al.[188] reported a ligand-dependent interaction between SHBG and two members of the fibulin family of extracellular matrix–associated proteins, fibulin-1D and fibulin-2, in the uterus. The physiologic significance of these observations is unknown, but it is possible that SHBG-fibulin interaction could regulate the local estradiol concentration within the myometrium. SHBG concentrations are increased in pregnancy, hyperthyroidism, liver disease, old age, inflammatory conditions, and by some medications such as estrogens and some antiepileptics.

KEY POINTS

- The rate-limiting steps in estradiol production by the ovary are the cholesterol transport from the outer to the inner mitochondrial membrane by the StAR protein in the theca interna cells and the aromatization of C19 androgens in the granulosa cells.
- Steroid biosynthesis in the ovary is regulated by LH and FSH and enhanced by two orphan members of the Ftz-F1 subfamily of nuclear receptors, the transcription factors SF-1 and LRH-1 through the regulation of CYP19A1, and other steroidogenic enzymes StAR, CYP11A1, HSD3B2, and CYP17A1.
- Estrogen and testosterone can alter each other's bioavailability through dynamic repartitioning on the allosterically coupled binding sites on SHBG and albumin proteins.

Estrogen Metabolism

Estradiol is metabolized through a series of the NADPH-dependent hydroxylation at C2, C4, C15, or C16 or oxidation reactions to form inactive or less active polar (hydroxylated and keto) metabolites as well as to nonpolar metabolites largely in the liver.[189] These compounds are conjugated in the liver by uridine UDP-glucuronosyltransferase 1-3, the product of the UGT1A3 gene that converts estrogenic compounds into water-soluble glucuronides and by sulfotransferase enzyme into sulfates that are excreted in the urine.[189] Estriol glucuronide and sulfate are the major metabolic products excreted in the urine of menstruating and pregnant women. Some of the estrogen conjugates are excreted through the bile duct into the intestine, partially hydrolyzed and reabsorbed, thus constituting an enterohepatic recirculation loop that can extend the half-life of estrogenic products.[190] As discussed earlier, hydroxylation of estradiol and estrone at C2 and C4 can form catechol estrogens that subserve different functional roles.

Mechanisms of Estrogen Action

Estrogens exert their physiological function by genomic as well as nongenomic mechanisms. The genomic actions of estrogenic compounds are mediated by two ER subtypes, which are encoded from distinct genes on different chromosomes: ERα (NR3A1) and ERβ (NR3A2) that regulate the ligand-dependent transcription of specific target genes by binding to DNA regulatory sequences. ERα is expressed in the mammary gland, uterus, theca cells of the ovary, adipose tissue, bone, testes and epididymis, stromal cells of the prostate, vascular endothelium, and hypothalamus and other brain regions. ERβ is found mainly in the granulosa cells of the ovary, adipose tissue, cardiovascular system, immune system, several brain regions, epithelial cells of the prostate, bladder, and colon.

Similar to other members of the nuclear hormone receptors, ERα and ERβ are composed of three distinct functional domains spanning amino- to carboxyl-terminal sequences: the NTD, the DBD, and the LBD[190] (Fig. 105.11). Additionally, two AF domains, AF1 and AF2, located within the NTD and LBD, respectively, regulate the downstream transcriptional activity through ligand-specific conformational gating.[191,192] Liganded ER translocates to nucleus and associates with coactivators/corepressors. These multiprotein complexes associate with specific DNA sequences—estrogen response elements—to modulate transcriptional signaling.

ER Isoforms: Structural Features, Homology, and Functional Dynamics. ERα and ERβ share the same three functional domains (LBD, DBD, and NTD). While NTD and DBD exhibit low sequence homology of 15% and 55%, respectively.[193] DBD possesses ~95% homology between ERα and ERβ that facilitates the formation of heterodimers between the two ER isoforms on the estrogen response elements (EREs). The NTD of the nuclear hormone receptors has substantial conformational heterogeneity as a result of intrinsically disordered (ID) regions. While this dynamic structure allows the AF1 region to fine-tune the transactivation function of the ER, it has prevented the successful crystallization of most of the NTDs. Functionally, the presence of ID regions affords facile recognition surfaces capable of associating with target molecules in diverse cell types. Secondary structural analyses of the ERα and ERβ NTD using network protein sequence analysis show limited structural organization in helical or β-sheet states, while more than 67% of ERα and 80% of ERβ NTDs contains random coil conformation.[194] These large sections of ID regions in NTD may provide a common mechanism for unconstrained conformational sampling of coordinate/energy landscape to identify distinct binding partners in tissues. It has also been proposed that AF domain may populate the folded conformational state in the presence of coregulators such that relative concentrations and/or affinity of the coactivator/repressor could amplify or abrogate the transcriptional activity.

A highly conserved DBD, with 95% homology between the two ER isoforms, adjoins the N-terminal transactivation domain (A/B domain).[19] The minimal consensus ERE, shared by ERα and ERβ, is a 13 base-pair inverted repeat-5′GGTCAnnnTGACC3′. However, two flanking base pairs (resulting in a 15-bp palindrome: 5′AGGTCAnnnTGACCT3′) substantially influence the ER:ERE affinity.[195,196] The ERE sequences modulate the on/off rates for the ER:ERE complexes as well as the formation of higher-order complexes including recruitment of coactivators. The conformational states of ERα DBD:ERE structures have been extensively characterized by several biophysical spectroscopy methods. Solution structures have been solved using NMR techniques to complement the high-resolution,

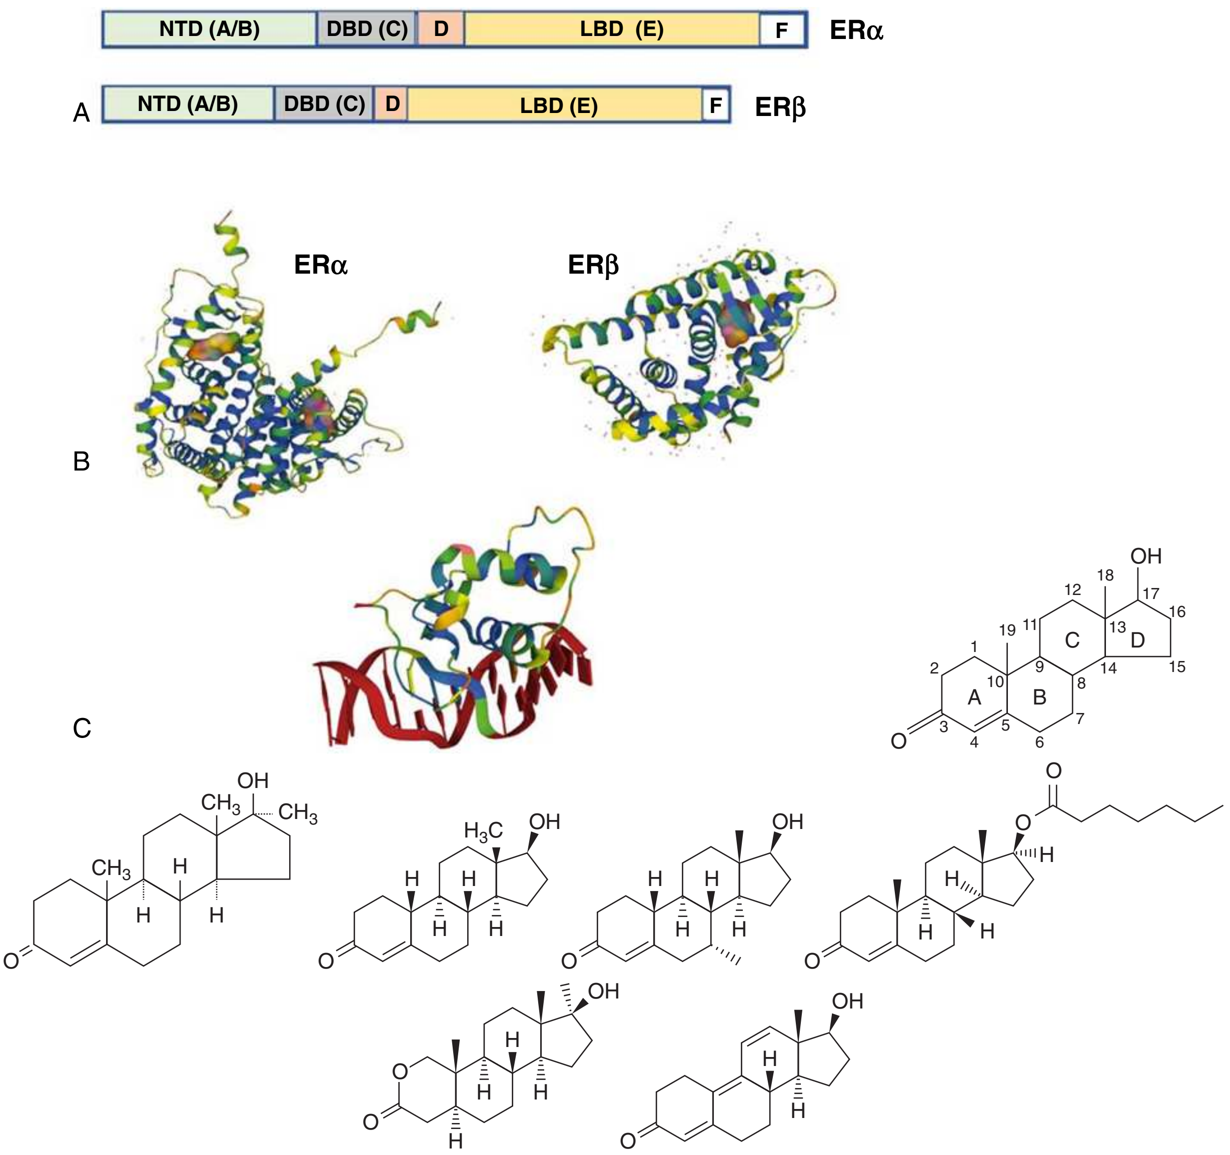

Figure 105.11 Schematic depiction of the various domains of the estrogen receptor (ER) subtypes, their crystal structure, and the three-dimensional structures of estradiol-bound ERα and ERβ. **A**, Schematic representation of the various domains of ERα and ERβ. **B**, Crystal structure of ER-DBD in complex with DNA-response element (obtained from 1LO1 submission in protein data bank). C, Three-dimensional structures of estradiol-bound ERα and ERβ, PDB structures 1A52 and 3OLS, respectively. *D*, hinge region; *DBD*, DNA-binding domain; *F*, C-terminal region; *LBD*, ligand-binding domain; *NTD*, N-terminal domain.

three-dimensional X-ray crystallographic studies.[197,198] These studies have shown a concerted role of P-box and D-box sequences in zinc finger domains. The cysteine-rich Zn finger subdomains coordinate with the two Zn^{2+} ions, P box associates with the ERE nucleotides, the D box has been shown to be present at the dimerization interface. The stoichiometry of ERE:ER complex formation has been actively debated in the literature with conflicting data suggesting that monomeric ER can associate with ERE half site or an ER monomer associating with ERE palindrome.[199]

The Ligand-Binding Domain. Organization of the LBD is a highly conserved structural feature among the members of the nuclear hormone receptor family. Similar to AR, the "E" domain of ER contains LBD spanning 11 α-helices (H1 to H12) with a hormone-binding pocket, a homo- or heterodimerization interface, and coregulator (activator or repressor) recruitment surface. The hormone-binding pocket in LBD mediates the ligand-induced conformational rearrangement and ensuing processes such as coregulator recruitment to AF2, dimerization, and translocation to the nucleus. ERα and ERβ retain overlapping three-dimensional arrangement even with a low overall sequence homology (55%).[193] Amino acid residues 223 to 343 and 404 to 457, which retain a significantly higher homology in ERα and ERβ appear to be buried on the interior, are protected from proteolytic degradation and participate in ligand binding. On the other hand, the sequences with lowest homology to ERβ are solvent accessible.[200] Both isoforms of ER-LBDs form dimers through the interactions spanning helices 10 and 11.

Ligand binding to ERα is accompanied by significant rearrangement in the orientation of helix 12. The hydrophobic ligand-binding pocket is formed by 22 residues. The crystal structure of 17β-estradiol-bound ERα LBD shows an important role of the two hydroxyl groups (3 and 17 positions) in the relative positioning of the ligand in the pocket. In ERα, the hydroxyl groups of the A and D rings form hydrogen bonds with Glu353, Arg394, and His 524 from helices H3, H5, and H11, respectively, and a water molecule.[201] However, there are notable changes in the two amino acid positions in binding pocket of ERα and ERβ: Leu384 and Met421 in ERα are replaced by Met336 and Ile373 in ERβ, respectively. While the changes do not alter the hydrophobicity in the pocket, the crystal structures show that the binding pocket of ERβ is slightly smaller than that of ERα.[202] Collectively, with the conserved spatial positioning of ligand-binding pocket residues and overall electrodensity map, the ERα and ERβ share agonist and antagonist ligands.

Coactivators. The pleiotropic effect of ER signaling on diverse tissues cannot be fully understood without accounting for the dynamic interaction of ER-associated coregulators. Over 200 coregulators have been identified that interact with ER to either enhance (coactivators) or inhibit (corepressors) transcription in a tissue-specific manner. Due to the heterogeneous expression of these coregulators in diverse tissues, their active role in mediating tissue-specific effects of ER is being increasingly recognized. While the coregulator proteins are thought to make higher-order complexes with unliganded or liganded ER states, many of them are epigenetic modifiers that exhibit enzymatic activities such as acetylation, methylation, and ubiquitination, thereby actively regulating transcriptional output. Coactivators belonging to members of SRC/p160 family, the histone acetyltransferase CREB-binding protein (CBP)/p300, ATP-dependent chromatin remodeling complexes like SWI/SNF, E3 ubiquitin-protein ligases, and steroid RNA activator (SRA) have been extensively characterized. Additionally, ERα and ERβ have been shown to differentially interact with the TATA box-binding protein (TBP), which has a central role in the basal transcription machinery. While TBP selectively binds to the ERα-NTD, it fails to associate with the ERβ-NTD and to potentiate ER-activated transcription. Most of the coactivators have been shown to share NR boxes or LxxLL motifs (x, any amino acid; L, Leucine), which stabilize their binding to ER LBD. Interestingly, the protein expression level of many of the coregulators of ER is under transcriptional control by estradiol, thereby providing a sensitive feedback mechanism for transcription regulation. Collectively, coregulators seem to play a critical role in mediating tissue-specific transcriptional outcomes by either physically stabilizing multiprotein complexes or altering post-transcriptional states of the in-tissue protein milieu. The net effect of these multilevel regulatory interactions results in a fine-tuned, ER-subtype–specific modulation of signaling pathways.

KEY POINTS

- Two estrogen receptor subtypes, ERα (NR3A1) and ERβ (NR3A2), modulate diverse physiological outcomes through either genomic (binding to specific DNA sequences to regulate ligand-dependent transcription of specific target genes) or direct nongenomic transcriptional events.
- Ligand-induced transcriptional control through interaction with coregulator families provides a facile mechanism for tissue-specific estrogen receptor-mediated effects.

INTRODUCTION

Hypogonadism in men is a clinical syndrome arising from failure of the testes to produce physiological amounts of testosterone (T) and/or normal numbers of spermatozoa due to pathologies or dysfunctions in one or more levels of the hypothalamic-pituitary-testicular (HPT) axis (see Chapter 105).

Androgen or T deficiency is synonymous with low circulating and target tissue concentrations of T, which lead to a variable range of androgen-dependent (androgen receptor-mediated gene transcription) physiological deficits, including defective spermatogenesis, manifesting as clinical features of hypogonadism. In contrast, primary/intrinsic disorders of spermatogenesis presenting as male infertility mostly exist in isolation, without overt evidence of T deficiency. This chapter addresses only the diagnosis and treatment of androgen deficiency in hypogonadism in the adult, while the management of spermatogenic disorders and delayed puberty are dealt with elsewhere (see Chapters 112 and 115 and 103).

Hypogonadism can be differentiated by the level of the underlying abnormality in the HPT axis. Testicular abnormalities give rise to primary hypogonadism, common causes of which include Klinefelter syndrome (KS) and cryptorchidism (Table 106.1), where low T concentrations and impaired spermatogenesis are coupled with elevated gonadotropins, reflecting the loss of negative feedback inhibition in the HPT axis. Hypothalamus or pituitary defects such as pituitary tumors and Kallmann syndrome (KallS) or normosmic isolated hypogonadotropic hypogonadism (nIHH) (Table 106.1) cause secondary hypogonadism, where low T concentrations and impaired spermatogenesis are associated with low or inappropriate normal gonadotropin concentrations. Multilevel abnormalities in the HPT axis can also coexist in hypogonadism,[1] usually with a predominant hormone pattern related to either primary (e.g., renal failure, aging) or secondary hypogonadism (e.g., alcohol abuse, systemic diseases) (Table 106.1).

Hypogonadism can also be differentiated by its underlying etiologies (Table 106.1). Organic hypogonadism, also known as classical or pathological hypogonadism, is caused by congenital, structural, vascular, inflammatory, or infiltrative diseases in the HPT axis, which are usually permanent and irreversible (Key Points: Definition and Classification). Functional hypogonadism is caused by suppression of gonadotrophin or T production, usually from conditions unrelated to pathology of the HPT axis, and may be reversible after correction or removal of the underlying disorder[2] (Key Points: Definition and Classification). The topic of T deficiency in aging and chronic illness is dealt with in more detail separately (see Chapter 107).

KEY POINTS: Definition and Classification

- Male hypogonadism is a clinical syndrome arising from the failure of the testes to produce sufficient testosterone to maintain secondary sexual, reproductive, and other androgen-dependent physiological functions.
- Consequences and clinical features of testosterone deficiency vary according to the stage of sexual development:
  - Ambiguous genitalia development characterizes fetal onset.
  - Delayed puberty characterizes childhood onset.
  - Sexual dysfunction, infertility, and alterations in adipose and musculoskeletal mass and function characterize adult onset.
- Organic hypogonadism is caused by structural, vascular, inflammatory, or infiltrative diseases in the hypothalamus-pituitary-testicular axis are recognized. These are usually permanent and irreversible.
- Functional hypogonadism is caused by conditions unrelated to pathology of the hypothalamus-pituitary-testicular axis and may be reversible after correction or removal of the underlying disorder.
- Functional hypogonadism associated with obesity/diabetes, opiate, and anabolic steroid abuse and advanced age is becoming increasingly prevalent.

It should be emphasized that male hypogonadism is a syndromic diagnosis characterized by suggestive clinical features in the presence of low T concentrations; as such, the underlying etiologies should be defined in order to ensure optimal management (Key Points: Diagnosis). Thus, differentiating primary from secondary hypogonadism has significant therapeutic implications. Spermatogenic defects in primary testicular disorders are not amenable to hormonal treatment, and fertility management is limited to options offered by assisted reproduction technologies. In contrast, dormant spermatogenesis in secondary hypogonadism can be stimulated or restored with appropriate exogenous gonadotropin therapy to promote fertility. Secondary hypogonadism arising from pituitary tumors will require specific treatment targeting tumor mass reduction and effects of pituitary hormone excess or deficiencies. Functional secondary hypogonadism associated with obesity, medications (e.g., opioid analgesics, anabolic steroids), or systemic illness is potentially reversible with weight reduction, discontinuation of medications, or successful treatment of or recovery from the underlying illness, respectively.

KEY POINTS: Diagnosis

- The diagnosis of hypogonadism should be made only in men with symptoms and signs consistent with androgen deficiency abetted by consistently and unequivocally low serum testosterone concentrations in fasting morning blood.
- Accurate and reliable measurement of testosterone is essential for the diagnosis of hypogonadism, but technical shortcomings and quality control issues can undermine this mission.
- Free testosterone measurement is indicated in the presence of sex hormone–binding globulin alterations, e.g., in obese and older men, and when testosterone is in the borderline low range.
- Measurement of gonadotrophins can differentiate secondary from primary hypogonadism, and direct further investigations to identify underlying etiologies and optimize specific treatment, e.g., for pituitary tumor or fertility promotion.

PATHOGENESIS

PRIMARY HYPOGONADISM

Both congenital and acquired causes can induce testicular damage and result in primary hypogonadism (Table 106.1). The hormonal profile is marked by elevated luteinizing hormone (LH) and follicle-stimulating hormone (FSH) concentrations, indicating Leydig cell damage with decreased sex steroid production and damage to the seminiferous tubules with impaired spermatogenesis and low inhibin B, respectively.

Klinefelter Syndrome

KS is the most frequent genetic disorder in men, with an estimated prevalence of one to two per 1000 men. Most men with KS have a supernumerary X chromosome (47,XXY), although other karyotypes (such as 48,XXXY, 48,XXYY) and in particular, mosaicisms (46,XY/47,XXY) are found in 10% to 20% of cases.[3] In 50% of patients, the additional X chromosome is from paternal origin and is the result of nondisjunction of sex chromosomes during the first meiotic division. The other 50% of cases have a maternal origin arising from nondisjunction in meiosis I or II, or during mitotic divisions in the early embryo.[3] Advanced parental age has been associated with the occurrence of both maternally and paternally derived KS.

Clinical Features and Diagnosis. The classic phenotype consists of small testes, gynecomastia, tall stature, hypergonadotropic hypogonadism, infertility, and learning disabilities (Fig. 106.1).[4] Other signs and symptoms may include cryptorchidism, decreased penis size, and signs of hypogonadism, such as decreased body hair growth, erectile dysfunction, and low libido (Fig. 106.1). It is important to emphasize that the clinical features in men with KS are highly variable. The classic phenotypic features may not always be extant (with the exception of testicular atrophy and infertility), resulting in diagnostic delay or nondetection (see later).

Diagnosis of KS is based on chromosome karyotype analysis. Few patients (<10%) are diagnosed during childhood or adolescence, when karyotype analysis is performed in boys with cryptorchidism, behavioral problems, or learning difficulties.[4] In adolescents and young adults, gynecomastia and small testis size can lead to the diagnosis. The majority of patients, however, are diagnosed in adulthood when they seek medical care for infertility. Remarkably, it is estimated that 50% to 75% of men with KS are never diagnosed, presumably because of the lack of characteristic clinical features drawing medical attention.[4]

Infertility. Most men (>95%) with KS are azoospermic, with elevated FSH, making it the most frequent genetic cause of azoospermia.[3] Testicular biopsy reveals mostly hyalinized seminiferous tubules with occasional Sertoli cells, as well as Leydig cell hyperplasia. Spermatozoa can be detected in the ejaculate in a limited number of patients (<10%, usually KS mosaic). In 30% to 50% of azoospermic men, focal spermatogenesis can be preserved, offering the opportunity for spermatozoa to be retrieved surgically by testicular sperm extraction (TESE) or microdissection TESE and used for intracytoplasmic sperm injection, with approximately 45% live birth rates in highly specialized centers (see Chapter 115).[4]

Hypogonadism. Almost all men with KS have elevated LH levels, reflecting some degree of Leydig cell dysfunction. T levels, are however more variable and as many as one third of patients can have T levels in the low-normal range. Testosterone replacement therapy (TRT) should be started in younger patients with delayed or incomplete puberty and in adult patients with hypogonadal symptoms and

TABLE 106.1 **Causes and classification of hypogonadism**

Organic or Classical Causes of Hypogonadism	Functional Causes of hypogonadism
Primary Hypogonadism	
Leydig cell dysfunction and impaired spermatogenesis: – *Klinefelter Syndrome* – Other (sex) chromosome disorders – Cryptorchidism (bilateral) – Congenital anorchia – Acquired anorchia (trauma, torsion, orchidectomy) – Orchitis (Mumps, HIV, brucellosis, leprosy, syphilis, tuberculosis, schistosomiasis, and filariasis) – Gonadotoxic cancer treatment (chemo/radiotherapy) – Noonan Syndrome – Myotonic dystrophy – Autoimmune polyglandular syndrome – *Hemoglobinopathies (Sickle cell disease, Thalassemia)* – Advanced age	– Drug-induced: ketoconazole, abiraterone – Renal failure[§]
Impaired spermatogenesis only: – *Y-chromosome microdeletions* – Sertoli-cell only syndrome – Spermatogenic arrest – *Cryptorchidism* (unilateral & bilateral) – *Orchitis* (*Mumps*, *HIV*, brucellosis, leprosy, syphilis, tuberculosis, schistosomiasis, and filariasis) – *Gonadotoxic cancer treatment (chemo/radiotherapy)*	
Secondary Hypogonadism	
– *Congenital IHH* – Congenital IHH in complex genetic syndromes – Congenital Combined Pituitary Hormone Deficiency – *Pituitary and non-pituitary tumors* – Nontumorous hypothalamic-pituitary diseases/injuries ■ Developmental hypothalamic and pituitary alterations (e.g. cysts) ■ Surgery ■ Radiotherapy ■ Traumatic brain injury ■ Apoplexy and other vascular accidents ■ Lymphocytic hypophysitis ■ Langerhans cell histiocytosis ■ Sarcoidosis ■ Infections (i.e. tuberculosis) ■ *Iron overload* ■ Empty sella	– *Hyperprolactinemia* – Cushing syndrome – Drug-induced ■ *Opiates* ■ *anabolic steroids* ■ *glucocorticoids* ■ GnRH analogs – Alcohol abuse[§] – *Severe obesity* – *Diabetes mellitus* – Systemic illnesses – Liver, heart, lung failure[§] – *Comorbid illnesses associated with ageing*[§] – Some sleep disorders – Nutritional deficiency – Excessive exercise

[§] Combined primary and secondary hypogonadism, but classified to usual predominant hormonal pattern.
Italic denotes the most frequent conditions.
Abbreviations: HIV: human immunodeficiency virus, IHH= Isolated Hypogonadotropic Hypogonadism, GnRH= Gonadotropin releasing hormone.

total and/or free T levels below the normal range. Some, but not all, pediatricians may prefer to proactively initiate TRT in puberty once LH becomes elevated to ensure normal progression and maximize virilization and psychosocial development. Normalizing T has a positive impact on erectile function, libido, moods, bone mineral density (BMD), muscle strength, body composition, and school or work performance. However, TRT can suppress residual spermatogenesis and influence to ability to recover occult sperm via testicular sperm extraction (TESE) (see Chapters 112 and 115 xxx). Fertility status should therefore be assessed, if possible, before starting TRT.

Associated Conditions. Men with KS have an increased risk for other medical and psychological conditions. As a consequence of androgen deficiency, Klinefelter patients have a lower BMD and a higher risk of fractures. However, low BMD can also be present in KS men who have T concentrations in the low-normal range. Follow-up of BMD via dual-energy x-ray absorptiometry (DXA) is recommended. Varicose veins/ulcers, venous thromboembolic events, and pulmonary embolism occur more frequently in patients with KS than in men from the general population. Men with KS have a higher risk for obesity with abdominal adiposity, type 2 diabetes, dyslipidemia, and the metabolic syndrome.[4] The prevalence of cardiovascular disease is higher, contributing to the observed increase in mortality in Klinefelter patients. Proactive screening and treatment of cardiovascular risk factors is recommended. The overall risk of cancer in men with KS is not increased. However, certain types of cancers occur more frequently. Breast cancer risk is approximately four

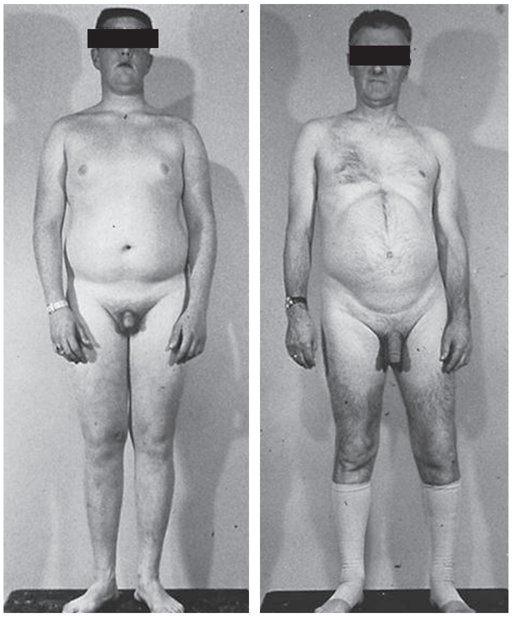

Figure 106.1 Variability in the degree of androgen deficiency manifested in men with Klinefelter syndrome. The man on the left, who has classic 47,XXY Klinefelter syndrome, demonstrates prepubertal androgen deficiency with eunuchoidal body proportions, small penis, sparse chest and pubic hair, poor muscle development, prepubertal fat distribution, and very small testes (2 mL bilaterally). The man on the right, who has mosaic 47,XXY/46,XY Klinefelter syndrome, demonstrates normal body proportions, penis size, and body hair but small testis size (8 mL bilaterally). (From Smyth CM, Bremner WJ. Klinefelter syndrome. *Arch Intern Med.* 1998;158:1309–1314; and Matsumoto AM, Bremner WJ. Testicular disorders. In: Melmed S, Polansky KS, Larsen PR, et al., eds. *Williams Textbook of Endocrinology*. 13th ed. New York: Elsevier; 2016:688–777.)

times higher in Klinefelter patients. The incidence of mediastinal germ cell tumors and hematological cancers is also increased. Autoimmune disorders, such as type 1 diabetes, hypothyroidism, and rheumatic disorders, appear to be more prevalent in men with KS. They can also have dental problems, retinal dysfunction, and tremor. Neurocognitive deficits and psychological morbidities are major problems in many Klinefelter patients. The most characteristic are learning difficulties, impaired speech and language skills (dyslexia), and impaired executive function. Anxiety, depression, autism, and schizophrenia also appear to occur more often in men with KS. Recent studies suggest there is an increase in criminality in KS patients compared with the general population.[4,5]

Other Sex Chromosome Disorders

Other sex chromosome disorders, such as 46,XX with a male phenotype, are discussed in Chapter 101.

Cryptorchidism and Spermatogenic Failure

Cryptorchidism is a prevalent condition affecting 2% to 4% of male full-term infants. Bilateral cryptorchidism is associated with many hypogonadal conditions (primary and secondary) and androgen resistance syndromes. Unilateral or bilateral cryptorchidism not associated with known causes of hypogonadism usually gives rise to isolated impairment of spermatogenesis with low sperm counts, normal T concentrations, and generally a selective elevation in FSH levels. Rarely, however, bilateral cryptorchidism causes Leydig cell failure as well, with low serum T and high LH and FSH. Azoospermia occurs in 50% to 60% and oligozoospermia in 75% to 100% of men with bilateral cryptorchidism. In unilateral cryptorchidism, azoospermia is present in 15% to 20% and oligozoospermia in 20% to 40% (see Chapters 114 and 115).

Cryptorchidism can be associated with hypospadias, infertility, and testicular cancer (testicular dysgenesis syndrome (see Chapter 114)).

Congenital Anorchia

Congenital anorchia is the absence of testicular tissue in 46,XY phenotypic males. In most cases, it is unilateral, and affected men are usually not hypogonadal. Bilateral anorchia in phenotypic males is rare (1:20,000 men). It is hypothesized that testicular torsion occurs when the testes descend into the scrotum during fetal development, resulting in testicular atrophy. As the external male genitalia are normally developed at birth (Fig. 106.2), testicular function had to be normal in first trimester of pregnancy (vanishing testis syndrome or testicular regression syndrome).

In patients with impalpable testes, undetectable antimullerian hormone (AMH) is suggestive of bilateral anorchia, while normal AMH levels predict the presence of intraabdominal testes (bilateral cryptorchidism) and a normal T response to human chorionic gonadotrophin (hCG) stimulation (1000–2000 IU three times weekly for 2 weeks).[6] Imaging studies and laparoscopy or surgical abdominal exploration are necessary for definitive exclusion of cryptorchidism.[7] Patients with bilateral congenital anorchia are infertile and require puberty induction and lifelong TRT.[8]

Acquired Anorchia

Scrotal trauma, damage to vascular structures during testicular surgery, testicular torsion, and orchidectomy (e.g., for testicular cancer) can lead to the loss of one or both testes. The remaining testis will usually hypertrophy to compensate for the loss of one testis in response to increased gonadotrophins.

Orchitis

Inflammation of the testis (orchitis) usually occurs together with inflammation of the epididymis (epididymitis). Mumps orchitis used to be a common cause of orchitis.[9] After introduction of widespread vaccination, the incidence of mumps orchitis decreased, although sporadic outbreaks are reported despite high vaccination coverage. Approximately 15% to 30% of adolescents and adult men who are infected with the mumps virus develop orchitis, which is bilateral in 20% to 40% of cases. Following mumps orchitis, testicular atrophy and decreased fertility can occur, although the development of azoospermia is rare and occurs more frequently in men with bilateral orchitis.

Primary hypogonadism used to be prevalent in men with acquired immunodeficiency syndrome (up to 30%–50%).[10,11] This is caused by orchitis induced by the human immunodeficiency virus (HIV) infection itself or secondary to opportunistic infections in immunocompromised patients, such as toxoplasmosis or cytomegalovirus infection. Since the introduction of highly active antiretroviral therapy, the prevalence of hypogonadism in men with HIV has decreased.[11]

Other infectious diseases, such as brucellosis, leprosy, syphilis, tuberculosis, schistosomiasis, and filariasis occasionally also affect the testis and can induce primary testicular failure.

Gonadotoxic Cancer Treatment

Cancer treatment with chemotherapy or irradiation can severely damage the testis and induce transient or permanent impairment of spermatogenesis and infertility. Often, male cancer patients have impaired spermatogenesis already at the time of cancer diagnosis, before any cytotoxic treatment is started.[12]

The spermatotoxicity of cancer treatments depends on the type and combination of agents and is dose-dependent. Irradiation of greater

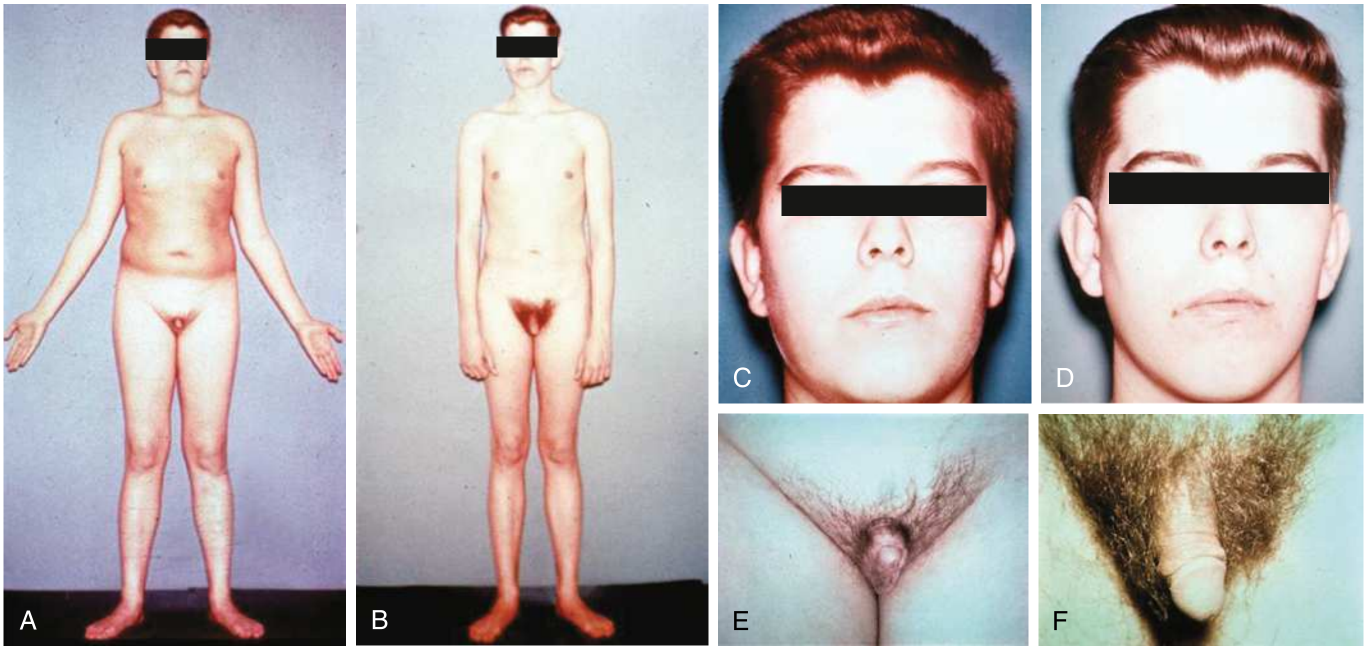

Figure 106.2 A 19-year-old patient with prepubertal androgen deficiency caused by congenital anorchia before (A, C, and E) and after (B, D, and F) 5 years of testosterone treatment. Before testosterone treatment, the patient had features of eunuchoidism, characterized by infantile genitalia (small penis and poorly developed scrotum); lack of chest, pubic, and facial hair; long arms and legs relative to height; and poorly developed muscle mass in the upper body with accumulation of fat in the face, chest, and hips. After testosterone treatment, there was an increase in penis size; an increase in chest, pubic, and facial hair with scalp recession and development of acne; an increase in muscle mass, particularly in the upper body; and loss of fat in the face, chest, and hips. (From Matsumoto AM. The testis. In: Felig P, Frohman LA, eds. *Endocrinology and Metabolism*. 4th ed. New York: McGraw-Hill; 2001:635–705; and Matsumoto AM, Bremner WJ. Testicular disorders. In: Melmed S, Polansky KS, Larsen PR, et al., eds. *Williams Textbook of Endocrinology*. 13th ed. New York: Elsevier; 2016:688–777.)

than 2.5 Gy to the testis, total body irradiation, and the use of alkylating agents (such as cyclophosphamide, melphalan, chlorambucil, busulfan, and procarbazine) are associated with the highest risk of developing prolonged azoospermia in men.[13] Other chemotherapeutic agents (such as cisplatin) can also affect spermatogenesis, resulting in severe oligospermia or azoospermia. Recovery is possible, but it can take months to years, and oligospermia will persist in a substantial number of men.[12] It is now standard of care to refer all patients of reproductive age with a recent cancer diagnosis for fertility counseling and sperm cryopreservation before any gonadotoxic treatment is started.

Chemotherapy and radiotherapy (>600 cGy) can also induce Leydig cell dysfunction, although Leydig cells are more resistant to gonadotoxic agents than the seminiferous epithelium. Long-term cancer survivors can develop compensated or primary hypogonadism later in life. In testicular cancer survivors, the risk for developing T deficiency was highest in men receiving high doses of cisplatin. Men with testicular cancer treated with standard chemotherapy or infradiaphragmatic radiotherapy had a higher risk of developing T deficiency compared with those treated with orchiectomy alone.[14]

Noonan Syndrome

Noonan syndrome is a relatively rare autosomal dominant disease with an estimated incidence of one in 1000 to 2500.[15] A genetic defect can be documented in 80% of cases with a *de novo* (66%) or inherited (33%) mutation in genes encoding for proteins of the RAS-MAPK pathway (*PTPN10* in 50% of cases).[15] Clinical manifestations are heterogeneous and include peculiar facial features (triangular-shaped face, hypertelorism, down-slanting palpebral fissures, micrognathia, and low-set ears), as well as short stature, coagulation disorders, and cardiomyopathy.[15] Cryptorchidism occurs in 70% of boys with Noonan syndrome. Delayed puberty is frequent, although T tends to normalize later in life.[16] Spermatogenesis may be compromised; this may result from cryptorchidism, but it can also be specific to the underlying mutations, as RAS plays a role in spermatogenesis.

Myotonic Dystrophy

Myotonic dystrophy type 1 (Steinert disease) is a rare autosomal dominant disorder affecting 1:8000 people and caused by expansion of *CTG* trinucleotide repeat in the dystrophia myotonica protein kinase gene (*DMPK*). It is characterized by myotonia (involuntary, sustained muscle contraction), muscle weakness/wasting, cardiac conduction abnormalities, frontal balding, and cataract. Testicular atrophy, infertility, and primary hypogonadism are common (80%) in men with myotonic dystrophy type 1. Myotonic dystrophy type 2 is less severe and is caused by *CTG* repeat expansion in the CCHC-type zinc finger, nucleic acid-binding protein gene (*CNBP*).

Autoimmune Polyglandular Syndrome

Mutations in the autoimmune regulator gene (*AIRE*) on chromosome 21 induce autoimmune polyglandular syndrome (APS) type 1. It is an autosomal recessive disorder, characterized by hypoparathyroidism, adrenal insufficiency, and mucocutaneous candidiasis, but other autoimmune diseases can also occur. Primary hypogonadism in adult men with APS is linked to the presence of antibodies targeting side-chain cleavage enzyme in the steroidogenic pathway and occurs in 5% to 7% of patients with APS. Azoospermia is rarely observed.[17]

Sickle Cell Disease

Homozygous sickle cell disease can be associated with primary testicular failure, but secondary hypogonadism can also occur. Vasoocclusion of testicular blood vessels resulting in recurring microinfarctions may be the cause, but other mechanisms have also been postulated. Men with sickle cell disease can also have impaired spermatogenesis.[18]

SECONDARY HYPOGONADISM

Secondary hypogonadism, also known as hypogonadotropic hypogonadism, may result from an intrinsic impairment of pituitary structure/function or a failure of hypothalamic gonadotropin-releasing hormone (GnRH) secretion. Secondary hypogonadism may also be the consequence of a combined dysfunction of hypothalamus and pituitary. Gonadotropin deficiency can be either isolated or combined with other pituitary hormone insufficiencies, and it may result from congenital or acquired diseases. Hypogonadotropic hypogonadism may potentially result from any pathology involving the hypothalamus-pituitary unit. As a consequence of these disorders, hypogonadism may occur alone or together with multiple hormone deficiencies. These conditions are discussed in more detail in chapters 4, 6-11, and 16. In this chapter, the secondary hypogonadism aspects will be addressed.

Congenital Isolated Hypogonadotropic Hypogonadism

Congenital isolated hypogonadotropic hypogonadism (IHH) was formerly known as idiopathic hypogonadotropic hypogonadism in order to denote the absence of structural abnormalities of the hypothalamus/pituitary. IHH has a global prevalence of one per 4000 to 10,000 males.[19] It is now known that mutations in multiple genes involved in GnRH secretion and/or action are the causes of IHH. Nevertheless, half of tested IHH patients still have no identifiable genetic defects.[20] Genes involved in IHH can be classified into (i) genes encoding factors, which play a role in normal differentiation, development, or migration of GnRH neurons from their early embryonal location in the olfactory placode to the hypothalamus and (ii) genes involved in normal GnRH secretion or action. Because the former processes take place in close association with developing axons of olfactory nerves, IHH arising from mutations in these genes is frequently associated with impairment in sense of smell. IHH with an-hyposmia is termed KallS, whereas IHH with normal sense of smell is called nIHH.

At least 30 genes have been implicated in IHH,[21] with an inconsistent genotype–phenotype correlation due to low penetrance and variable expressivity among subjects carrying the same mutation. A familial aggregation is recognized in over 40% of cases. IHH, originally deemed to be a monogenic disorder, is increasingly recognized as an oligogenic (multiple genes) disease, thus amplifying the spectrum of inheritance patterns.

Kallmann Syndrome. KallS represents approximately half of IHH cases. Although IHH is characterized by a limited genotype–phenotype correlation, mutations in some genes tend to be more specifically associated with KallS[21] (Table 106.2). The most frequent amongst these is *ANOS1* (formerly denoted as *KAL1*), encoding an extracellular matrix glycoprotein termed anosmin-1, which participates in the normal embryonal migration of GnRH neurons. Mutations of *ANOS1* are found in up to 60% of familial cases of KallS and in up to 15% of sporadic forms. *ANOS1* is located on chromosome Xp22.3 and, accordingly, familial forms of KallS due to *ANOS1* mutations follow an X-linked inheritance pattern. Other genes are involved in KallS development, but, unlike *ANOS1*, their mutations could also be responsible for nIHH or even congenital combined pituitary hormone deficiency (CPHD) (Table 106.2). These mutations may arise *de novo* or be inherited with autosomal dominant or recessive transmission. Increasingly more cases are attributed to two or more genes (oligogenicity) that do not follow the classical Mendelian inheritance pattern. The list of implicated genes is constantly growing, but among the most frequently involved are *FGFR1* (formerly named *KAL2*), *PROKR2*, *PROK2*, *SEMA3A*, and *CHD7* (Table 106.2). *FGFR1* is the first gene associated with autosomal dominant forms of KallS, although now autosomal recessive or oligogenic forms due to *FGFR1* mutations are also known. FGF8 is one of FGFR1 ligands, and mutations in its codifying gene are rare causes of KallS/nIHH.

CHD7 (Table 106.2) was initially recognized as the gene responsible for the CHARGE syndrome (coloboma, heart defects, atresia choanae, retarded growth, genital hypoplasia, ear abnormalities/deafness). Later, *CHD7* mutations were found in attenuated forms of CHARGE syndrome that had underdevelopment of genitalia and smell impairment as major features. Moreover, missense *CHD7* mutations with partial loss of function were associated with KallS or even nIHH. At present, *CHD7* and *FGFR1* are the most frequently implicated in KallS/nIHH, with autosomal transmission.

PROKR2 and *PROK2* mutations are implicated in KallS/nIHH (Table 106.2). In up to 20% of familial forms of KallS/nIHH attributable to *PROKR2/PROK2,* biallelic mutations (homozygous or compound heterozygous) denote autosomal recessive transmission. However, several subjects are heterozygous, indicating autosomal dominant or oligogenic transmission. Nonetheless, rare *PROKR2/PROK2* mutations are also prevalent in the general population, so finding *PROKR2/PROK2* mutations in KallS/nIHH subjects may not yield a conclusive genetic diagnosis. *PROKR2/PROK2* mutations are rarely associated with nonreproductive phenotypic defects that are observed in KallS or nIHH (see later).

After the first recognition in a family with several KallS cases, *SEMA3A* mutations have been recognized in an increasing number of KallS patients in a heterozygous state (suggesting autosomal dominant inheritance), sometimes in association with other KallS/nIHH genes (suggesting oligogenicity) (Table 106.2).

Besides an/hyposmia, KallS is characterized by clinical features of fetal-onset hypogonadism, which include cryptorchidism, microphallus, and hypospadias, and of delayed puberty. Additionally, nongenital/nonolfactory defects can be variably present (Box 106.1). It is noteworthy that hypogonadism can resolve in up to 10% to 15% of cases of KallS/nIHH.[22] Reversal to eugonadism, usually in adulthood, is denoted by increase in testes size and a sustained normalization of T and gonadotropin levels after withdrawal of T treatment. The mechanism of reversal is still unclear. It has been proposed that the increase in circulating T levels from treatment could upregulate the expression of genes involved in GnRH secretion. Moreover, in animal models, hypothalamic cells have the potential to differentiate into GnRH neurons, thus replacing those missing from fetal development. Reversal has been documented in subjects with different genetic defects, including *FGFR1, PROKR2, ANOS1,* and *CHD7* (Table 106.2). However, reversal may not be permanent, and relapse has been documented in a number of patients who had apparently recovered from hypogonadism.

Normoosmic Congenital Isolated Hypogonadotropic Hypogonadism. The distinction between KallS and nIHH is based on the presence or absence of an/hyposmia. However, the dividing line is not always clear-cut. Indeed, several genes may be implicated in both disorders, and the same mutation may even cause both clinical conditions in different patients (Table 106.2). Similar to KallS, nIHH may also be associated with nongenital disorders. Despite the overlap between KallS and nIHH, there are genes whose mutations have never been associated with smell impairment and, for this reason, are considered specific to nIHH (Table 106.2). These include *GNRH1*, *GNRHR*, *KISS1*, *KISS1R*, *TAC3*, and *TACR3*. Notably, mutations in these genes linked with nIHH are also not associated with any other nongenital conditions (Table 106.2). *GNRHR*, encoding the GnRH receptor, was the first gene causing nIHH that was identified, and it is the most frequent genetic defect in nIHH patients. Mutations in *GNRH1*, encoding GnRH, are rare causes of this disorder. The *KISS1* gene encoding kisspeptin 1 is expressed in the hypothalamus, whereas *KISS1R*, formerly known as *GPR54*, encoding its cognate G protein-coupled receptor, is expressed in the hypothalamus and pituitary. The interaction of kisspeptin 1, secreted by hypothalamic KISS1 neurons, with KISS1R is responsible for the normal processing and release of GnRH and thought to be pivotal for the onset of puberty. Biallelic mutations in *KISS1R* have been found in nIHH-affected families, suggesting autosomal recessive

TABLE 106.2 Genes Most Commonly Associated with Congenital Isolated Hypogonadotropic Hypogonadism (IHH)

Gene *Encoded Protein*	Chr Location	Biological activity	Inheritance	KallS	nIHH	Other Phenotypes	IHH Reversal	Nonreproductive Clinical Features
ANOS1 *Anosmin-1* *Extracellular matrix glycoprotein*	Xp22.31	Normal embryonal migration of GnRH neurons	X-linked	X	-	-	X	Yes
FGFR1 *Fibroblast growth factor receptor 1* *Receptor*	8p11.23	Broad range of functions during embryogenesis, including the development of olfactory bulbs	AD/AR/OG/DN	X	X	CPHD ±SOD	X	Yes
FGF8 *Fibroblast growth factor 8, ligand of FGFR1*	10q24.32	Development of forebrain, olfactory and GnRH system, skeletal structure and heart	AD/OG	X	X	CPHD	-	Yes
FGF17 *Fibroblast growth factor 17* *Ligand of FGFR1*	8p21.3	Development of dorsal frontal cortex	OG	X	X	-	-	?
HS6ST1 Heparan-sulphate 6O-sulpho-transferase-1	2q14.3	Catalyzes the transfer of sulfate to heparan sulfate, in FGFR1 signaling	OG	X	X	-	X	?
IL17RD Interleukin-17 receptor D	3p14.3	Negative regulator of FGFR1	OG	X	X	-	-	?
CHD7 *Chromodomain helicase DNA binding protein 7* *Transcriptional regulator*	8q12.2	Development of neural crest forebrain, craniofacial bones, and heart	AD/AR/OG/DN	X	X	CHARGE	X	Yes
PROK2 *Prokineticin-2* *Ligand of PROKR2*	3p13	Development of olfactory bulbs	AD/AR/OG	X	X	-	-	No

TABLE 106.2 Genes Most Commonly Associated with Congenital Isolated Hypogonadotropic Hypogonadism (IHH)—cont'd

Gene *Encoded Protein*	Chr Location	Biological activity	Inheritance	KallS	nIHH	Other Phenotypes	IHH Reversal	Nonreproductive Clinical Features
KISS1 *Kisspeptin-1* *Ligand of KISS1R*	1q32.1	Secreted by the neurons of arcuate and anteroventral periventricular nuclei; regulation of GnRH neurons	AR	-	X	-	-	No
KISS1R *G protein-coupled receptor for kisspeptin-1*	19p13.3	Expressed in hypothalamic GnRH neurons Regulation of GnRH neurons	AR	-	X	-	-	No
TAC3 *Tachykinin-3 Ligand of TACR3*	12q13.3	Secreted by neurons of arcuate nucleus; regulation of the secretion and homeostasis of GnRH neurons	AR	-	X	-	X	No
TACR3 *G protein-coupled receptor for TAC3*	4q24	Expressed in hypothalamic GnRH neurons Regulation of the secretion and homeostasis of GnRH neurons	AR	-	X	-	X	No
LEP *Leptin* *Adipocyte-specific hormone*	7q32.1	Regulation of food intake and energy expenditure	AR	-	X	Morbid obesity	-	No
LEPR *Leptin receptor* *Single-transmembrane domain receptor for leptin*	1p31.1	Expressed in hypothalamus Regulation of food intake and energy expenditure	AR	-	X	Morbid obesity	-	No
FSHB *β-subunit of FSH*	11p14.1	Together with α-subunit makes FSH, which stimulates Sertoli cells	AR	-	-	Isolated FSH deficiency	-	No
LHB *β-subunit of LH*	19q13.33	Together with α-subunit makes LH, which stimulates Leydig cells	AR	-	-	Isolated FSH deficiency	-	No

Chr, Chromosome; *KallS*, Kallmnn syndrome; *nIHH*, normosmic isolated hypogonadotropic hypogonadism; *IHH*, isolated hypogonadotropic hypogonadism; *AD*, autosomal dominant; *AR*, autosomal recessive; *OG*, oligogenic; *DN*, *de novo*; *CPHD*, combined pituitary hormone deficiency; *SOD*, septooptic dysplasia; *CHARGE*, coloboma, heart defects, atresia choanae, retarded growth, genital hypoplasia, ear abnormalities/deafness; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone; *GnRH*, gonadotropin-releasing hormone.

BOX 106.1 Extragenital Nonolfactory Congenital Defects Occurring in Congenital Hypogonadotropic Hypogonadism

Neurologic Defects	Nonneurological Defects
Sensorineural deafness	Cleft palate
Nystagmus	Cleft lip
Color blindness	Dental agenesis (hypodontia)
Bimanual synkinesia (mirror movements)	Syndactyly or other hand-foot malformations
Cerebellar ataxia	Renal agenesis or malformations
Spastic paraplegia	Pes cavus
Seizure	

inheritance. Mutations in *KISS1* are much rarer, but they seem to follow the same inheritance pattern. *TAC3* encodes tachykinin-3, precursor of neurokinin-B. It is secreted by hypothalamic neurons in the arcuate nucleus and infundibular region afferent to GnRH neurons. Its cognate receptor TACR3 is expressed in the same area. They interact in normal GnRH secretion, and their mutations have been recognized in nIHH families following an autosomal recessive inheritance pattern. Similar to KallS, nIHH can also spontaneously revert (Table 106.2), most frequently in those with *GNRHR* mutations.

Selective Deficiency of Luteinizing or Follicle-Stimulating Hormone. This is a rare form of nIHH characterized by a selective deficiency of one of the gonadotropins due to mutations in genes encoding for the β chain of LH (*LHB*) or FSH (*FSHB*). Boys with *LHB* mutations are characterized by severe hypogonadism with low T levels and undetectable LH, small testicles, and azoospermia. They fail to initiate puberty and, in some cases, present in adulthood with severe hypogonadism. *FSHB* mutations are even rarer. The few affected males have normal T and LH, but undetectable FSH. Azoospermia is the predominant clinical feature.

Congenital Hypogonadotropic Hypogonadism in Complex Genetic Syndromes

These rare conditions are usually diagnosed in infancy and childhood from the clustering of characteristic developmental and dysmorphic clinical features. These patients are usually introduced into adult practice in transitional clinics for continued endocrine management.

Prader-Willi syndrome. Prader–Willi Syndrome (PWS) is a rare genetic condition with a prevalence of one in 10,000 to 30,000 live births due to deletions (65%–75% of PWS patients), maternal uniparental disomy (23%–30%), or imprinting defects (3%) in a critical region on chromosome 15q11-q13.[23] Several genes important for hypothalamic functioning are located in the 15q11-q13 region, and most PWS clinical features are attributable to hypothalamic dysfunction, including hyperphagia with food obsession leading to pathological obesity, behavioral disorders, increased pain threshold, temperature instability, and sleep apnea.[23] Endocrine dysfunctions in PWS derive from deficient hypothalamic stimulation of the pituitary. PWS subjects therefore frequently have coexisting hypopituitarism, with somatotropic and gonadotropic axes most affected (almost 100% of subjects).[23] Hypogonadism in PWS can also have a primary testicular component in up to 60% of patients, with severe seminiferous tubule hypoplasia and high FSH, even though T and LH are low.

Laurence-Moon-Bardet-Biedl syndrome. (Laurence–Moon) Bardet–Biedl syndrome is an autosomal recessive disease with a prevalence of one in 125,000 to 175,000.[24] More than 20 genes have been associated with this syndrome, all with important roles in cellular cilia development and function.[24] Hypogonadotropic hypogonadism is a frequent finding, together with multiple malformations (eyes and retina, mouth and teeth, hands and feet, kidney), neurologic alterations (cognitive impairment, developmental delay, ataxia), growth retardation, and obesity.[24]

Septo-optic dysplasia. Septooptic dysplasia is a rare condition with a prevalence of around one in 10,000, characterized by midline and forebrain abnormalities, including absent septum pellucidum and optic nerve and pituitary hypoplasia.25 Hypopituitarism is observed in 40% of patients. Multiple endocrine axes may be affected in this condition, and the deficiencies may accumulate throughout life.[25] A genetic defect is found only in a limited proportion of patients. Most cases are sporadic, although familial forms are recognized based on mutations of genes involved in the normal forebrain development, including *HESX1*, *SOX2*, *SOX3*, and *OTX2*.[25]

DAX-1 mutations. DAX-1 mutations are associated with a syndromic condition characterized by the combination of primary adrenal insufficiency (adrenal hypoplasia) and congenital secondary hypogonadism. *DAX-1*, located on chromosome Xp21.2, encodes an orphan receptor expressed in the adrenal, gonads, hypothalamus, and pituitary and participates to the development of these structures. Accordingly, hypogonadism in this syndrome is a combination of primary (testicular) and secondary (hypothalamus-pituitary) dysfunction. Clinical manifestations of hypogonadism are variable, with subjects presenting with normal or delayed puberty and different degrees of altered spermatogenesis. Due to the mixed origin of hypogonadism, patients with *DAX-1* mutations do not have an optimal response to gonadotropin therapy.

Congenital Combined Pituitary Hormone Deficiency

Mutations in transcription factors involved in the development of pituitary may cause congenital CPHD. Further details on CPHD are provided in Chapters 5 and 14.

Pituitary and Nonpituitary Tumors

Pituitary tumors are mainly adenomas that are usually intrasellar masses and represent 10% of all the intracranial neoplasms. Hormone deficiency, including secondary hypogonadism, may result from space-occupying destructive effects, which are more common for macroadenomas,[26] and/or from a specific inhibiting effects of hormone excess. Typically, prolactin-secreting adenomas can impair gonadotropin release through downregulation of GnRH, whereas adrenocorticotropic hormone (ACTH) hypersecretion can induce hypogonadism because of cortisol excess.

Nonpituitary tumors may be either intrasellar or suprasellar and affect gonadotropin secretion due to a space-occupying destructive effect and/or pituitary stalk disconnection. The most common primary tumors in the hypothalamus-pituitary region include craniopharyngioma, meningioma, germ cell tumors, chordomas, lymphoma, and glioma. In addition, this region may be also affected by intracranial metastasis from distant primary malignancies.

Nontumorous Hypothalamic-Pituitary Diseases/Injuries

Developmental. Developmental. Cystic lesions including Rathke's cleft, arachnoid, and dermoid cysts can affect the hypothalamus and pituitary. Secondary hypogonadism occurs as a result of gonadotroph damage or from hyperprolactinemia (pituitary stalk disconnection).

Surgery and Radiotherapy. Surgery and radiotherapy. While pituitary or hypothalamus surgery commonly causes multiple pituitary hormone deficiencies, external beam radiotherapy produces more selective effects. Gonadotrophs are more likely to be injured by cranial radiation doses greater than 40 Gy, but lower doses can impair their function when radiotherapy targets the pituitary directly.

Traumatic Brain Injury. Traumatic brain injury results in deficiency of at least one pituitary hormone in up to 40% of patients[27] depending on the severity of injury. Secondary hypogonadism, together with growth hormone (GH) deficiency, is the most frequent occurrence, with an incidence of approximately 15%.[27,28] The hormone impairments may occur several months after the traumatic event, but they can also revert spontaneously over time.

Apoplexy is a rare complication of pituitary adenomas. It results from hemorrhage or infarction of pituitary, traumatic brain injury, hypotension (including postpartum hemorrhage, so-called Sheehan syndrome), and rarely, some endocrine stimulation tests.[29] Pituitary apoplexy presents acutely with headache, visual disturbances, nausea and vomiting, photophobia, and meningism. Acute endocrine deficiencies may occur; among these, the most frequent is ACTH/cortisol deficiency that may cause life-threatening Addisonian crises. Secondary hypogonadism is evident at presentation in 40% to 75% of apoplectic patients.[29]

Lymphocytic hypophysitis. Lymphocytic hypophysitis is an inflammatory condition of the pituitary thought to be autoimmune-mediated, but the exact pathogenesis is poorly understood. It occurs more frequently during pregnancy and postpartum and is also associated with the newly introduced checkpoint inhibitor immunotherapies such as ipilimumab and nivolumab. Deficiencies in gonadotropins, vasopressin (leading to diabetes insipidus) and ACTH are the earliest and most frequent abnormalities.

Langerhans cell histiocytosis. Langerhans cell histiocytosis is a rare systemic disease characterized by uncontrolled proliferation of Langerhans cells, a specific cell type of the monocyte-macrophage lineage. Secondary hypogonadism and GH deficiency are the most frequent anterior pituitary deficiencies.[30]

Sarcoidosis. Sarcoidosis is a systemic disorder of unknown etiology characterized by the development of noncaseating granulomas in multiple organs and tissues. Hypothalamic or pituitary involvement is rare and leads to diabetes insipidus and anterior pituitary hormone deficiencies.

Iron Overload. Iron overload. Congenital iron metabolism disorders (i.e., hemochromatosis) or congenital or acquired diseases (haemoglobinopathies) requiring frequent blood transfusions may lead to iron overload in several tissues, including liver, heart, pancreas, and pituitary. Iron deposition seems to have a predilection for gonadotrophs, so that iron overload conditions are often complicated by severe secondary hypogonadism without impairment of other hormone axes.

Empty Sella. Empty sella is an anatomic and radiologic finding of herniation of the subarachnoid space within the sella turcica, which causes a variable degree of flattening of the pituitary. Pituitary deficiency is identified in up to 20% of patients, and gonadotropin deficiency is described in up to 30% of these.[31]

Drug-induced

Anabolic androgen steroids. Anabolic androgenic steroids are synthetic derivatives of T with modifications aimed at increasing the anabolic over the androgenic actions of the steroid. These are mainly used as illicit enhancers of physical performance in almost any sport at any level. There have also been attempts to use these drugs to improve quality of life in cachectic cancer patients. Although modified structurally, these androgens will inhibit GnRH-gonadotropin secretion, with consequent suppression of testicular function (both steroidogenesis and spermatogenesis), thus inducing secondary hypogonadism. The topic is described in detail in Chapter 110.

Opiates. Opiates are normally used as analgesic medications, but their abuse as chronic addictive substances has become increasingly prevalent in recent years.[32] Strong opiates (such as morphine, fentanyl, methadone, heroin) cause secondary hypogonadism in up to 90% of men, irrespective of route of administration. Hypogonadism occurs more rarely with buprenorphine, a partial μ-opioid agonist, used as an alternative to methadone for opiate withdrawal treatment.[33] Hypogonadism is due to an inhibitory effect of opiates on GnRH resulting in suppressed LH and T levels without affecting FSH. In heroin addicts, but not in chronic oral opioid users and abusers, sex hormone-binding globulin (SHBG) is elevated. It is generally underappreciated that hypogonadal symptoms are very common with chronic use of opiates.[33] These include low libido, erectile dysfunction, delayed ejaculation, decreased BMD, and depression. The use of opiate antagonists, such as naltrexone, may reverse some features of hypogonadism. Sexual function improves with naloxone treatment even before normalization of T levels, suggesting a direct effect of opiates on male sexuality.[33]

GnRH analogs. GnRH analogs are synthetic long-acting analogs of native GnRH. In men, they are usually administered intramuscularly monthly to once every three months for the treatment of advanced prostate cancer. After an initial and transient increase in gonadotropin and T concentrations (flare effect), GnRH analogs induce the downregulation of GnRH receptors. This leads to a sharp decline in gonadotropin and T levels. This is the desired therapeutic effect aimed at reducing the androgenic stimulation of prostatic malignant cell proliferation. However, the resulting severe hypogonadism is associated with troublesome side effects, including hot flushes, sexual dysfunction, fatigue, depression, osteoporosis and fragility fractures, gain in fat mass and loss of lean mass leading to metabolic consequences (dyslipidemia, impaired glucose tolerance, hypertension), and increased cardiovascular risk.

DIAGNOSIS OF HYPOGONADISM

CLINICAL DIAGNOSIS

The clinical features of androgen deficiency can be distinguished by the stage of sexual development at onset (Table 106.3). Fetal-onset hypogonadism causing incomplete development of male genitalia can present at birth with microphallus, hypospadias, bifid scrotum, and cryptorchidism. Prepubertal onset hypogonadism results in a failure of T-induced secondary sexual development, giving rise to a specific clinical picture of eunuchoidism (Fig. 106.2). These include underdeveloped infantile external genitalia, small, smooth unpigmented scrotum with small testes (<4 mL), lack of secondary sexual hair (pubic, axillary, chest, limbs, and face) with no male escutcheon or temporal hair recession, poor muscle development, female body fat distribution (hips and chest), unbroken high-pitched voice without laryngeal enlargement, and eunuchoidal body habitus of long arms and legs. Gynecomastia, lack of sexual interest, spontaneous erections, and nocturnal emission with an immature and diffident demeanor complete the clinical picture, which can persist into adulthood if diagnosis is delayed. Osteopenia and reduced hematocrit are common.

Postpubertal or adult-onset hypogonadism arises from the inability to maintain previously established androgen-dependent functions such as sexual behavior/activity, spermatogenesis, muscle/bone mass, and facial/body/pubic hair. Clinical features include sexual dysfunction (decreased sexual interest and activity, reduced spontaneous/nocturnal erections, and erectile impotence), infertility (defined as an inability to father children with at least weekly unprotected vaginal intercourse for at least 12 months) with reduced testicular volume, particularly in primary hypogonadism, gynecomastia, hot flushes, fine, dry, wrinkling, smooth facial skin, height loss from vertebral compression fractures, fragility fractures, and a normochromic normocytic anemia. Depending on the severity and duration of androgen deficiency, some loss of secondary sexual hair may be present. However, adult secondary sexual characteristics such as genitalia, scrotum, larynx, and vocal cords generally do not regress to their prepubertal states. Less specific

TABLE 106.3 Symptoms and Signs Suggestive of Androgen Deficiency in Adult Men

Specific	Suggestive	Nonspecific
– Incomplete or delayed sexual development – Loss of body/pubic hair – Very small testes (<6 mL)	– Reduced sexual desire/drive (libido) and activity – Decreased spontaneous erections – Erectile dysfunction – Gynecomastia – Eunuchoidal body proportions – Height loss, low-trauma fracture, low bone mineral density – Hot flushes or sweats	– Decreased energy, motivation, initiative, self-confidence – Feeling sad or low, depressed mood – Poor concentration and memory – Sleep disturbance, increased sleepiness – Mild unexplained anemia (normochromic, normocytic) – Reduced muscle mass and strength – Central obesity

From Bhasin S, Cunningham GR, Hayes FJ, Matsumoto AM, Snyder PJ, Swerdloff RS, Montori VM; Task Force: Endocrine Society. Testosterone therapy in men with androgen deficiency syndromes: an Endocrine Society clinical practice guideline. J Clin Endocrinol Metab. 2010;95(6):2536–2559.

features may include lack of drive or confidence, low moods or dysthymia, low energy or vitality, poor concentration, sleep disturbance, increased (central) body fat, and reduced muscle mass and strength with or without physical limitations. The nonspecific and variable clinical picture of postpubertal hypogonadism overlaps with that commonly encountered in older men associated with obesity and comorbidities, rendering a clinical diagnosis of androgen deficiency in this population particularly challenging (see Chapter 107) (Table 106.3).

Clinical evaluation of a patient suspected of hypogonadism should include a targeted history and focused physical examination aiming to address the following questions:

- What symptoms and signs are compatible with androgen deficiency? If so, can they be differentiated from any coexisting nonspecific symptoms?
- When was the likely time of onset (fetal, prepubertal, or postpubertal), duration/severity of putative hypogonadism?
- What is the likely etiology of hypogonadism? Is it reversible?
- What may be the likely benefits and risks of hormone treatment if hypogonadism is confirmed?

History

The history should include enquiries into:

- Neonatal or childhood development (hypospadias, cryptorchidism, growth or learning problems), pubertal onset milestones (appearance of pubic hair, growth spurt, nocturnal emission, and shaving), history of testicular insults (toxins, chemotherapy, trauma/torsion, surgery, or infection [e.g., mumps orchitis]).
- Sexual, reproductive, and androgenic functions including reduced sexual interest (libido), decreased spontaneous morning erections, decline in frequency of sexual intercourse or masturbation, erectile dysfunction, marital or other relationship status, previous paternity, hot flushes, loss of facial/body/pubic hair, decreased shaving frequency, breast enlargement or tenderness, height loss, history of low-impact fractures or osteoporosis, and decreased muscle mass and muscle strength affecting physical performance or activity.
- General health including chronic respiratory disease, major organ failure of the heart, liver, or kidney, hemoglobinopathies/blood transfusions, haemochromatosis, diabetes mellitus, ischemic heart disease, thromboembolic disease, headaches, and visual disturbance.
- Past and current medications, (opioid analgesics, glucocorticoids, psychotropics, chemotherapy, radiotherapy, 5α-reductase inhibitors, GnRH analogs, antiandrogens, and anticoagulants).
- Recreational drugs (anabolic steroids, cannabis, opiates).
- Smoking and alcohol intake.
- History of eating disorders.
- Excessive exercise.
- History of sexually transmitted infections, e.g., chlamydia, gonorrhea, syphilis.
- History of excessive snoring, which may suggest obstructive sleep apnea.
- Lower urinary tract symptoms (LUTS).
- Past history of prostatic diseases—benign hyperplasia or cancer.
- Mental state—anxiety, depression, irritability, poor concentration, low vitality/energy, low self-esteem.
- Family history of delayed puberty, anosmia, infertility, haemochromatosis, thromboembolic diseases, androgenic alopecia, and prostate cancer.

A history of obstructive sleep apnea, prostatic diseases, and cardiovascular and thromboembolic diseases are important in assessing the potential risks of TRT.

Examination

Physical examination of a patient suspected of hypogonadism should include assessment of:

- Body habitus (height, arm span, kyphosis), body weight (body mass index) and body fat distribution, muscle development, acne, and sebum production.
- Secondary sexual hair distribution in the face, chest, limbs, axillae, pubis, and male escutcheon.
- External genitalia—penile size/length, position of external urethral meatus.
- Testes location, size, contour, and consistency.
- Prostate by digital rectal examination (in adults over 40 years of age).[34]
- Breast examination.
- Sense of smell.
- Visual fields, iris, and optic fundoscopy (if indicated).
- Mental state and demeanor.

A eunuchoidal body habitus, defined as an arm span exceeding height by greater than 5 cm, is suggestive of prepubertal onset hypogonadism because of delayed long bone epiphyseal closure. Patients with KS may have disproportionally long legs, with lower body segment (symphysis to floor distance) exceeding the upper body segment (crown to symphysis distance). The presence of excessive acne over the shoulders and upper back and excessive sebum production in the forehead should alert the possibility of anabolic steroid abuse, especially in a man with well-developed musculature (presenting with infertility).

Testes position, size, contour, and consistency should be assessed by careful palpation, using a Prader orchidometer or calipers for documenting testicular volume. This should be followed by palpation to locate other scrotal contents: epididymides, vasa deferentia, hydrocoele, varicocoele, and cough impulse.

The size of the testis provides a simple and convenient clinical measurement of the seminiferous tubular mass (which constitutes 98% of the total testis volume). Normal adult testis volume is between 15 and 30 mL (3.5–5.5 cm in length and 2–3 cm in width). Testis volume may be slightly reduced in secondary hypogonadism but is usually significantly reduced in primary hypogonadism and infertility, being the hallmark of KS, where the testes are characteristically small (<3 mL) and firm in consistency. Testis volume measurement is useful in assessing pubertal development, its onset being indicated by testis volumes of greater than or equal to 4 mL. Testis volume remaining at less than 4 mL in an adult patient is therefore suggestive of prepubertal-onset hypogonadotropic hypogonadism. Testis volume of greater than 6 mL in hypogonadotropic patients indicates some degree of seminiferous tubule maturation has taken place and is associated with a favorable fertility outcome in response to gonadotrophin treatment in adulthood.[35]

Examination of the genitalia and scrotum is best performed with the patient initially in a supine position, followed by inspection and palpation for the presence of a varicocele (resting and with Valsalva maneuver) or a cough impulse in the spermatic cord in the upright position.

Digital rectal examination of the prostate may reveal an enlarged smooth gland, induration, or the presence of nodule Detection of undiagnosed prostate pathologies is important in assessing potential risks before starting TRT in middle-aged or older (>40 years) patients.

Breast examination, with the patient supine, should use the thumb and index finger to define the margin of any firm breast tissue from the surrounding soft fatty tissue, allowing the diameter of gynecomastia to be assessed with calipers.

The presence of anosmia or hyposmia (usually tested in the clinic with prepared odorants or more formal olfactometry using the commercially available University of Pennsylvania Smell Identification Test), bimanual synkinesis, cleft lip and/or palate, and hypodontia (agenesis of one or more teeth) point to the diagnosis of KallS. Additional phenotypic features such as severe obesity, short stature, hearing loss, polydactyly, syndactyly, visual impairment, external ear abnormalities, and learning difficulties are encountered in complex syndromes such as PWS, Lawrence–Moon/Bardet–Biedl syndrome, CHARGE syndrome, and septooptic dysplasia.

Examination of visual fields by confrontation is important in the context of expanding pituitary or hypothalamic tumors, and visual acuity and fundoscopy for retinal or optic nerve abnormalities in secondary hypogonadism.

LABORATORY DIAGNOSIS

Testosterone

In men presenting with symptoms and signs suggestive of androgen deficiency, the diagnosis of hypogonadism must be confirmed by documentation of unequivocally and consistently low levels of serum (total and/or free) T (Key Points: Diagnosis).

Blood sampling for measurement of T needs to take into account some physiological variations in serum T concentrations in order to minimize preanalytical noise and maximize the reliability in confirming T deficiency. Serum T concentrations in an individual vary from minute to minute,[36] day to day,[37] and also diurnally,[38] being highest in the early morning (7:00 a.m.–8:00 a.m.) and lowest (up to 25% lower than morning values in young men, but less in older men) in the late afternoon (4:00 p.m.–5:00 p.m.), when serum T can occasionally fall well below the normal range in men with intact reproductive function.[36] It follows that a single low serum T result may not by itself be abnormal and is insufficient to confirm the diagnosis of hypogonadism. It is imperative therefore to confirm an initial low T with at least one, if not two, further measurements. Serum T is transiently suppressed (by 25%–30%) after food intake,[39] so that measurements should be performed after an overnight fast. Acute or critical illnesses, major trauma, and surgery reduce T and gonadotropin production due to temporary suppression of the HPT axis.[40] It is therefore advisable to avoid measuring T in acutely ill patients or in those recovering from acute illnesses in the previous 3 to 6 months. It is also important to be aware of other causes of transient low T, e.g., medications, particularly opiate analgesics and glucocorticoids, malnutrition (eating disorders), and excessive strenuous exercise. In summary, the biochemical confirmation of clinically suspected hypogonadism should be based on measurements of T on fasting morning (before 11:00 a.m.) blood samples obtained on at least two different days preferably four weeks apart.

Testosterone Measurements. The accurate measurement of T (total) with a reliable and well-validated assay is a prerequisite in establishing the diagnosis of hypogonadism. Most clinicians rely on automated nonextraction immunoassays performed in hospital clinical chemistry laboratories using multianalyzer platforms. Though economic, convenient, and hence prevalent, these methods show considerable analytical variabilities between different assays and laboratories[41] due to suboptimal measurement precision, compounded by inappropriate calibration and the use of peer comparison rather than accuracy-based external quality control. Although these automated platform assays can perform reasonably well within the male physiological range,[42] the accuracy of T measurements progressively decreases at lower concentrations, rendering results in the hypogonadal and borderline-low range less reliable.

Mass spectrometry-based methods, which include serum extraction and a chromatography step (gas chromatography–mass spectrometry or, more commonly, liquid chromatography-tandem mass spectrometry [LC-MS/MS]), are considered the state-of-the-art methods for the measurement of T. They offer improved sensitivity and accuracy over a wide range, though incurring higher costs and decreasing sample throughput,[43] but are nevertheless not immune from interlaboratory variation and standardization issues. Currently, the availability of mass spectrometry methods for T measurement is still patchy in most hospital and community practices, where immunoassays continue to be employed. Whether immunoassay or LC-MS/MS is used, it is important for individual laboratories to optimize and standardize T measurements through stringent external quality assurance (EQA). Clinicians should only rely on T results provided by laboratories certified or verified by accuracy-based external quality control.

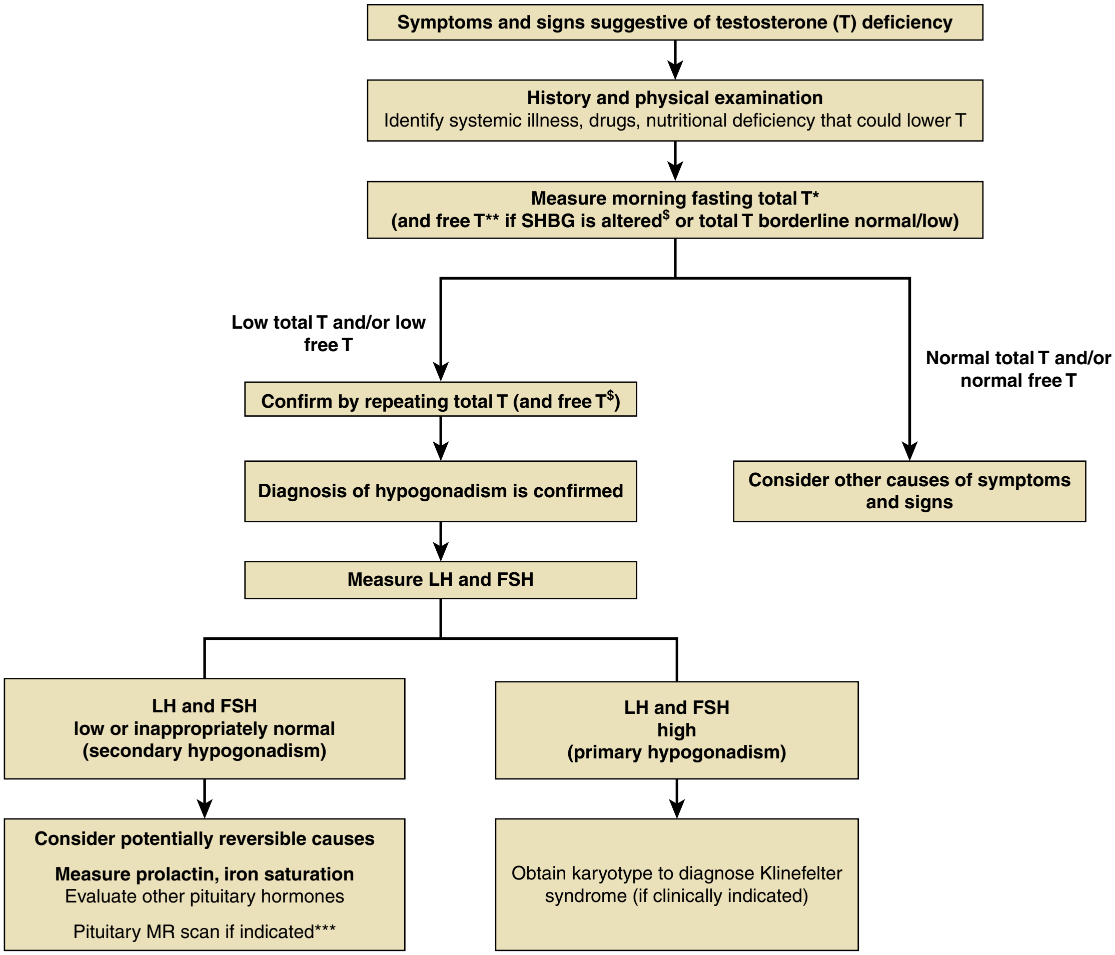
Total and Free Testosterone. T secreted from the testes is transported in the circulation bound to plasma proteins to prevent rapid diffusion across lipid-rich capillary cell membranes into tissues. Total T in the circulation is the sum of fractions bound mainly to SHBG (40%–60%) with high affinity (1.6×10^{-9} mol/L), to albumin (40%–50%) with lower affinity (1.0×10^{-4} mol/L), and minor fractions to orosomucoid and cortisol-binding protein, with only a small proportion (1%–3%) being unbound as the free hormone.[44] According to the free hormone hypothesis, only this small unbound fraction can freely access target tissues to induce androgenic biological actions.[45] T loosely bound to albumin can dissociate in slower-flowing circulations and potentially access some target tissues, e.g., liver, brain. The combined free and albumin-bound fractions of T are referred to as "bioavailable T."

The synthesis and secretion of SHBG in the liver is regulated by many hormonal, metabolic, and nutritional factors. Consequently, SHBG concentrations are frequently altered in commonly encountered physiologic and pathological conditions (Table 106.4). Serum total T measurements are affected by changes in SHBG levels without altering the free or intracellular (biologically active) T concentrations. Therefore, the biochemical confirmation of hypogonadism by total T alone can be confounded when SHBG levels are decreased or increased, leading respectively to spurious over- or underdiagnosis. Conditions that decrease SHBG (e.g., obesity, type 2 diabetes) can lower total T concentrations in eugonadal men into the subnormal range while free T remains normal, leading to overdiagnosis of hypogonadism. The European Male Aging Study found that obese men with low total T (and low SHBG) in the presence of normal free T did not show evidence of androgen deficiency, but low free T, even in the presence of normal levels of total T in aging men (with high SHBG), was associated with sexual symptoms and other evidence compatible with hypogonadism.[46] Conditions that increase SHBG (e.g., advanced age, HIV infection, thyrotoxicosis, cirrhosis) can maintain or raise total T concentration in the normal or high-normal range even though free T is low, and the diagnosis of hypogonadism is potentially overlooked.[46] It follows that free (or bioavailable) T should be measured in conditions that alter SHBG concentrations where total T is a less reliable indicator of gonadal status (Fig. 106.3). For similar reasons,

TABLE 106.4 Conditions that may Alter SHBG Concentrations

Increase	Decrease
– Ageing	– Obesity
– Thyrotoxicosis	– Diabetes
– Liver disease	– Hypothyroidism
– HIV infection	– Acromegaly, GH treatment
– Anticonvulsants	– Androgens, progestins, glucocorticoids, tyrosine kinase inhibitors
– Estrogens, SERMs, tamoxifen, cyproterone	– Nephrotic syndrome
– Malnutrition	– Polymorphisms in *SHBG* gene
– Polymorphisms in *SHBG* gene	

HIV, Human immunodeficiency virus; *SERMs*, selective estrogen receptor modulators; *GH*, growth hormone; *SHBG*, sex hormone–binding globulin.
(From Bhasin S, Cunningham GR, Hayes FJ, Matsumoto AM, Snyder PJ, Swerdloff RS, Montori VM; Task Force: Endocrine Society. Testosterone therapy in men with androgen deficiency syndromes: an Endocrine Society clinical practice guideline. J Clin Endocrinol Metab. 2010;95(6):2536–2559.)



Symptoms and signs suggestive of testosterone (T) deficiency
History and physical examination
Identify systemic illness, drugs, nutritional deficiency that could lower T
Measure morning fasting total T*
(and free T** if SHBG is altered$ or total T borderline normal/low)
Low total T and/or low free T
Normal total T and/or normal free T
Confirm by repeating total T (and free T$)
Diagnosis of hypogonadism is confirmed
Consider other causes of symptoms and signs
Measure LH and FSH
LH and FSH low or inappropriately normal (secondary hypogonadism)
LH and FSH high (primary hypogonadism)
Consider potentially reversible causes
Measure prolactin, iron saturation
Evaluate other pituitary hormones
Pituitary MR scan if indicated***
Obtain karyotype to diagnose Klinefelter syndrome (if clinically indicated)

Figure 106.3 Algorithm for the diagnostic evaluation of adult men suspected of hypogonadism. *The 2.5th percentile of reference range for total T harmonized to CDC standard in healthy nonobese young men is 264 ng/dL (9.2 nmol/L). This limit could be used for total T assays that are CDC-certified. For laboratories that are not CDC-certified and do not participate in an accuracy-based quality control program, the reference range may vary considerably depending on the assay and reference population used. Using the lower limit of the range established in local laboratories may not always accurately identify men with hypogonadism. **A harmonized reference range for free T has not been established, so reference ranges may vary considerably depending on the specific equilibrium dialysis method or the algorithm used to calculate free T. Therefore, until a harmonized reference range is available, the lower limits proferred by local laboratories may be used. $Conditions in which measurement of free T is recommended, where SHBG levels may be altered, are listed in Table 106.5. ***Perform pituitary imaging (MRI) to exclude pituitary and/or hypothalamic tumor or infiltrative disease in severe secondary hypogonadism (serum T <150 ng/dL [5.2 nmol/L]), panhypopituitarism, persistent hyperprolactinemia, or symptoms or signs of tumor mass effect (such as new-onset headache, visual impairment, or visual field defect) are present. *CDC*, Centers for Disease Control; *FSH*, follicle-stimulating hormone; *LH*, luteinizing hormone; *MRI*, magnetic resonance imaging; *SHBG*, sex hormone–binding globulin; *T*, testosterone. (Figure adapted from Bhasin S, Brito JP, Cunningham GR, et al. Testosterone therapy in men with hypogonadism: an Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab.* 2018;103:1715–1744.)

free T measurement is also informative when total T is at the borderline of the lower limit of normal (see "Reference range and thresholds" later and Fig. 106.3)[47] (Key Points: Diagnosis). Nevertheless, it is important to emphasize that total T remains a robust and well-tried measure of testicular function in most situations, especially in classical hypogonadism. Current guidelines unanimously recommend total T as the first line investigation for the diagnosis of suspected hypogonadism[1,2,48] (Fig. 106.3).

Measurement/Calculation of Free Testosterone. Free T concentrations should ideally be measured directly after serum dialysis or ultrafiltration to separate the bound from the free hormone. These state-of-the-art methods are technically demanding and expensive, and availability is limited to only a few reference and commercial laboratories. In routine practice, clinicians usually rely on calculated free T derived from total T, SHBG, and albumin concentrations using several algorithms[44,49] mostly based on affinity constants of T to the binding proteins. The accuracies of different algorithms vary when validated against directly measured free T concentrations. The most widely used is the Vermeulen law of mass action calculations,[50] which correlates well with measured free T and performs well in clinical scenarios across a wide range of SHBG concentrations in men, even though the results have a systematic positive bias.[49]

Bioavailable T is measured by ammonium sulfate precipitation of SHBG-bound T, with the addition of tritium-labeled T tracer to indicate the percentage of non–SHBG-bound T. This is a relatively cumbersome method involving radioactive reagents. Although bioavailable T can also be calculated from total T, SHBG, and albumin,[50] fewer clinical data are available to support its application, compared with free T, in the diagnosis of hypogonadism.

Free T tracer analog immunoassays, though widely available in commercial laboratories, are imprecise, and results are influenced by changes in SHBG; their use is not recommended.[41] Free androgen index (T/SHBG × 100), commonly used in women for the assessment of hirsutism, is not a valid surrogate for free T in men because of the relatively high levels of T compared with SHBG. Furthermore, the feedback regulation of T in the HPT axis in response to changes in SHBG produces a nonlinear relationship between T and SHBG, which is not accurately described by the ratio.

Reference Ranges and Thresholds. Reference ranges for total and free T vary considerably between laboratories and localities due to differences in assay methodologies, calibrators, and the constituents of the reference population. Clinicians have to rely on reference ranges provided by their local laboratories, some of which are of uncertain provenance. To harmonize reference ranges across different geographic regions, local results from four large cohorts of community-dwelling men in the United States and Europe were recently cross-calibrated against the reference mass spectrometry method of the Centers for Diseases Control (CDC). The harmonized reference range for total T in young (aged 19–39 years) healthy nonobese men was 264 to 916 ng/dL (9.2–31.8 nmol/L) representing the 2.5th to 97.5th percentiles and 303–852 ng/dL (10.5–29.5 nmol/L) using the 5th to 95th percentiles. Individual laboratories and EQA schemes can now calibrate their total T results to the CDC reference method so that clinicians may make use of the internationally harmonized reference range.

Serum T concentration declines gradually with age, mostly within the physiological range, but with greater rates of decline in men with obesity and comorbidities.[51] Currently, there is insufficient evidence to support the need for an age-adjusted Z-score approach for the T reference range,[52] and most laboratories continue to use the T-score approach, with reference range based on healthy nonobese men under 40 years of age.[1,2]

T concentrations in the population have a Gaussian continuous distribution, so that a single cutoff value below which hypogonadism pertains is unlikely to exist. Furthermore, there is evidence to suggest that different T threshold levels apply to individual androgen deficiency symptoms or functions.[53] While there is no consensus on what is considered a subnormal T level, many studies have demonstrated that clinical signs of androgen deficiency increase when T levels fall below 260 to 317 ng/dL (9–11 nmol/L).[54-57] This also corresponds to the 2.5th to 5th centile of the CDC-harmonized population reference range (see earlier). Therefore, a threshold "range" or "grey zone" around 260 to 317 ng/dL (9–11 nmol/L), rather than a discreet level of T, would more accurately reflect the available evidence. In clinical practice, there is a prevalent view that men with T concentrations below 230 ng/dL (8 nmol/L) are likely to be clinically hypogonadal, whereas men with T above 346 ng/dL (12 nmol/L) are probably eugonadal, while those with T between 230 and 346 ng/dL (8–12 nmol/L) can be considered to have borderline values when free T measurements can be helpful (see earlier).[2,47]

Given the lack of standardization in free T assays and uncertainties surrounding different algorithms for calculating free T, the reference range for free T is less well established than that for total T. A level around 6.5 ng/dL (225 pmol/L), ranging from 5.0 to 7.0 ng/dL (170–240 pmol/L), has been suggested as the lower limit of normal free T.[41,55,57] Until a harmonized and validated reference range for measured or calculated free T is available, individual laboratories will need to establish their own locally.

Other Hormone Measurements. Circulating T is metabolized to a more potent androgenic metabolite, 5α-dihydrotestosterone (DHT), in target tissues such as prostate, liver, and hair follicles by 5α-reductase 1, 2, and 3 (SRD5A1, SRD5A2, and SRD5A3).[58] DHT in the circulation is almost solely derived from the peripheral conversion of secreted T in target tissues. Measuring blood levels of DHT is therefore not useful in the assessment of testicular function in the diagnosis of hypogonadism and is only performed in rare suspected cases of 5α-reductase deficiency (see Chapters 101 and 102).

Estradiol (E2) plays an important part in male skeletal physiology, fat deposition, and sexual function.[59] Less than 15% of circulating E2 in men is secreted directly by the testes; the remaining 85% is converted from androgen precursors (predominantly T) by the aromatase (CYP19A1) enzyme in tissues such as fat, brain, testis, and bone. Measurement of serum E2 is generally uninformative in the diagnosis of hypogonadism, but it is indicated in the investigation of gynecomastia (see Chapter 108) and in rare cases of aromatase deficiency (see Chapters 101 and 102). Serum E2 levels in men are low (around 10–53 pg/mL [38–196 pmol/L]), and immunoassays usually lack the sensitivity of more reliable LC-MS/MS-based methods.

Further Investigations to Identify Etiologies of Hypogonadism. Gonadotropins should be measured in men with confirmed hypogonadism to distinguish primary from secondary hypogonadism, which then entrains further investigations to identify underlying etiologies (Fig. 106.3) (Key Points: Diagnosis).

Gonadotropins are now routinely measured by modern immunoassays, which have sufficient sensitivity to distinguish between normal and low basal levels of LH and FSH in adult patients without the need for dynamic GnRH stimulation test. The latter test is poorly characterized and cannot consistently distinguish IHH from self-limited delayed puberty (see Chapter 103) or hypothalamic from pituitary pathologies. Despite the pulsatile secretion of gonadotropins, there is generally no difficulty in identifying unequivocally elevated levels encountered in primary hypogonadism; thus, a single measurement for LH and FSH usually suffices.

In men with primary hypogonadism, chromosome karyotyping may be needed, especially in the presence of suggestive clinical features such as small (<6 mL) testes, gynecomastia, and azoospermia, to diagnose possible KS (47,XXY in 90%) (Fig. 106.3). Karyotype analysis is carried out in cultured peripheral blood lymphocytes. To confirm suspected KS mosaicism (47,XXY/46,XY), karyotype analysis is performed on cultured skin fibroblasts or testicular tissue. Selective elevation of FSH (with normal LH and T) in infertile men with oligozoospermia or azoospermia suggests severe primary spermatogenic failure, commonly due to Y chromosome microdeletion (see Chapters 112 and 115), which is not amenable to hormonal/medical management.

In secondary hypogonadism, further investigations to exclude possible hypothalamus or pituitary pathologies such as pituitary tumors, KallS, IHH, hyperprolactinemia, and iron overload are indicated (Fig. 106.3), especially in younger patients. These should include measurement of serum prolactin, iron saturation, and/or serum ferritin, assessment of other anterior pituitary hormone excess (e.g., Cushing syndrome acromegaly) or deficiency (hypopituitarism, diabetes insipidus), and magnetic resonance imaging (MRI) of the pituitary and hypothalamus. The latter is required in the presence of clinical evidence of pituitary mass effects such as visual disturbances, recent-onset headache, hydrocephalus, or significant hyperprolactinemia

(>100 ng/mL or 2000 mIU/L) suggestive of a pituitary prolactinoma (see Chapter 4).

In the evaluation of presumed secondary hypogonadism in middle-aged and older men with low T, where these red-flag findings of pituitary pathologies are usually absent, the cost-effectiveness of MRI of the pituitary has been questioned.[60] The reported prevalence of major hypothalamic-pituitary lesions that require intervention remain very low until T concentrations fall to less than 5.2 nmol/L (<150 ng/dL)—this has been proposed as the action threshold for MRI to improve diagnostic yield in the investigation of functional secondary hypogonadism.

In patients with IHH, the advent of next-generation sequencing has improved our understanding of monogenic, digenic, and oligogenic etiologies of the heterogeneous disorders associated with GnRH deficiency.[61] This has raised the prospects of molecular genetics diagnosis of mutations affecting GnRH regulation, the GnRH receptor, or the *LH* gene, guided by family history (sporadic, X-linked, autosomal dominant/recessive) and the presence of somatic phenotypic syndromic features such as anosmia, hearing loss, bimanual synkinesis, cleft lip and/or palate, polydactyly, hypodontia (agenesis of one or more teeth), and unilateral renal agenesis (Box 106.1). Making a genetic diagnosis of IHH (and differentiating from self-limited delayed puberty) may confer advantages in targeted treatment to minimize virilization deficits/delays, optimize fertility, and promote personalized approaches to genetic counseling (see Chapter 103).

Hypogonadism is associated with osteopenia or osteoporosis and increased risk of low-trauma or fragility fracture.[59] All patients with confirmed hypogonadism should undergo DXA scanning to measure BMD in both spine and hip and calculate fracture risk with fracture risk calculators such as FRAX to inform management and follow-up.[62] However, the cost-effectiveness of BMD measurement for optimizing bone health outcomes, especially in fracture and fall prevention, in hypogonadal men has not been formally assessed.

TREATMENT OF HYPOGONADISM

TESTOSTERONE REPLACEMENT THERAPY

Indications

TRT is used to treat androgen-deficient men with a diagnosis of primary and secondary hypogonadism. The aim of TRT is to improve hypogonadal symptoms, restore circulating T levels to physiological levels, induce or maintain secondary sexual characteristics, and reverse or prevent the consequences of T deficiency (Key Points: Treatment). Current guidelines recommend TRT only in men diagnosed to be hypogonadal on the basis of symptoms and signs of androgen deficiency, as well as repeatedly low T levels.[1,2]

KEY POINTS: Treatment

- Testosterone replacement therapy for confirmed organic hypogonadism is well-established and highly efficacious.
- Patient-important efficacy outcomes and long-term safety of testosterone treatment in men with functional hypogonadism have not yet been clearly demonstrated.
- Appropriate efficacy assessment and safety monitoring should be performed during maintenance of testosterone treatment.
- Gonadotropin induction of spermatogenesis with luteinizing hormone-like and follicle-stimulating hormone preparations allow the majority of isolated hypogonadotropic hypogonadal patients to achieve natural fertility or assisted conception.

Testosterone Preparations

TRT can be delivered by many preparations, with different pharmacokinetics and routes of administration (Table 106.5). Replacing relatively obsolete injectable or implantable T preparations, transdermal gels and long-acting depot injections are now the most frequently used. The choice of the therapeutic regimen depends on its pharmacokinetics, the patient's preference, local availability and cost, and treatment burden.[1] An overview of the recommended dose, interval of administration, advantages, and disadvantages is given in Table 106.5.

Endogenous T secreted by the testis into the circulation is converted to E2 by the aromatase enzyme and to the more potent androgen DHT by 5α-reductase enzymes. All three hormones are required to achieve the full spectrum of male sexual/reproductive and nonreproductive physiological functions. The TRT preparation of choice should therefore also be convertible to E2 and DHT, ideally mimicking endogenous T.

Parenteral Testosterone Preparations

Intramuscular Injectable Preparations. Injected natural T has a short circulatory half-life of approximately 10 minutes. To prolong the half-life and improve solubility in the vehicle oil, T esters, such as T enanthate and T cypionate, have been developed for intramuscular injection. Shortly after injection, serum T increases to supraphysiological levels, followed by a gradual decrease over 1 to 3 weeks. Large excursions in serum T concentrations, which can be associated with symptomatic fluctuations in some patients, are the main disadvantage. The risk of developing erythrocytosis is higher with intramuscular injections due to supraphysiological peak T concentrations.[63,64] There is no advantage in using mixtures that combine short- and longer-acting T esters in one injection.

Testosterone undecanoate (TU) is available as an ultra–long-acting T formulation in a castor oil base injected every 10 to 14 weeks. A rare adverse effect, occurring in 15 to 19/1000 injections, is the development of coughing and dyspnea shortly after injection, possibly due to pulmonary oil microembolization.[63-65] It is advisable to observe patients for 20 to 30 minutes after TU injections.

Subdermal Implantation of Testosterone Pellets. T pellets are implanted subcutaneously in the gluteal region or lower abdominal wall via a minor surgical procedure. Data documenting the efficacy of T pellets in improving hypogonadal symptoms are scarce,[66] but the infrequent administration and relatively stable T concentrations are appreciated by patients.

Subcutaneous Injections. Subcutaneous administration of T enanthate via an autoinjector is under development. Weekly injections of 75 mg yielded stable T concentrations.[67]

Transdermal Testosterone Preparations

Testosterone Patches. One patch contains 2 or 4 mg of T applied on the back, abdomen, upper arms, or thighs. Skin irritation and rash from the excipients are frequently reported, leading to treatment discontinuation.[63]

Testosterone Gels. Transdermal hydroalcoholic T gels are one of the most frequently used formulations to treat hypogonadism. The gel is applied every morning to the upper arms, shoulders, or abdomen. T is then absorbed to form a reservoir in the dermis, from which it is slowly released into the circulation. Transdermal T gels are easy to use and have few side effects. Skin irritation is rare compared with patches. Secondary exposure to women or children via accidental transfer of the gel has been reported, causing virilization. This risk can be minimized by instructing patients to wash their hands and avoid close skin contact with others after

TABLE 106.5 Overview of Available Testosterone Preparations

Route of Administration	Formulation	Starting Dose/Interval	Advantages	Disadvantages
Intramuscular injections	Testosterone enanthate	250 mg Every 2–3 weeks	Relatively inexpensive Flexibility of dosing	Requires IM injections. Excursions in T concentrations may be associated with fluctuating symptoms
	Testosterone cypionate	250 mg Every 2-3 weeks	Relatively inexpensive Flexibility of dosing	Requires IM injections Excursions in T concentrations may be associated with fluctuating symptoms
	Testosterone propionate (not available in United States)	50-100 mg Every 3–5 days		Frequent IM injections, not suited for chronic treatment T concentrations fluctuate
	Mix of testosterone esters (Sustanon)	One vial 250 mg Every 2–3 weeks	Relatively inexpensive Flexibility of dosing	Regular IM injections Excursions in T concentrations may be associated with fluctuating symptoms
	Testosterone undecanoate	1000 mg at week 0 and 6, and then every 12 weeks United States: 750 mg at week 0 and 4, and then every 10 weeks	Infrequent administration	Local discomfort after IM injection of large volume (3 or 4 mL) Coughing/dyspnea within 15–30 minutes of injection in small number of patients (15–19/1000 injections)
Subcutaneous implants	Implantable pellets (only available in United States and Australia)	150–450 mg every 3 months or 600–1200 mg every 6 months	Infrequent administration Relatively stable T concentrations	Requires minor surgical insertion Pellets may extrude Local hematoma or infection rarely
Subcutaneous injections	Testosterone enanthate	75 mg Once weekly	Ease of application	Increased blood pressure, injection site reactions, headache
Transdermal	T patch (only available in some countries)	2 or 4 mg per patch 4 mg every 24 hours	Ease of application	Skin irritation
	T gel	Available as 1%, 1.62%, 2% gel in unit-dose packets or via a metered-dose pump system Dose dependent on the formulation: 50 mg for 1% T gel; 81 mg for T 1.62%; 60 mg for 2% T gel Once daily	Ease of application Flexibility of dosing	Risk of transfer to female partner or child Variable T concentrations from day to day
	T solution (Axiron)	60 mg one to two times/day in the axillae		Risk of transfer to female partner or child Variable T concentrations from day to day
Oral	Testosterone undecanoate capsules (not available in United States)	40-80 mg/capsule Two to three times/day	Convenient administration Avoids first-pass metabolism	Short half-life, requires multiple daily dosing Ingestion with fatty meal Fluctuating T levels due to variable absorption
	Modified testosterone undecanoate	237 mg/capsule Two times/day	Ingestion with regular meal Avoids first-pass metabolism	Twice daily administration
	Testosterone buccal bioadhesive tablet	30 mg/tablet Two times/day	Avoids first-pass metabolism	Local gum irritation Alteration of taste No dose titration
Intranasal	Nasal gel	One pump of 5.5 mg per nostril three times/day	Rapid absorption Avoids first-pass metabolism	Local nasal side effects Multiple applications per day

applying the gel and by covering the gel application area with clothes. A major advantage is that treatment can be stopped quickly if side effects occur.[63,64]

Oral Testosterone Preparations. Orally ingested T is rapidly inactivated by the liver (first-pass metabolism). To avoid this first-pass effect, modified androgen preparations have been developed.

TU in castor oil capsules is absorbed via the gut lymphatic system, thus avoiding hepatic first-pass metabolism.[63] To increase absorption, the capsules should be ingested with a (fatty) meal twice or thrice daily.

A modified form of oral TU using a self-emulsifying drug delivery system has been designed to increase the solubilization of lipophilic testosterone. This twice-a-day oral TU formulation has recently been approved by the US Food and Drug Administration (FDA) for treatment of hypogonadism in the United States. In clinical trials, it produces mean serum T concentrations in the mid-normal range in 87% of patients, with a positive impact on hypogonadal symptoms.[68]

Transbuccal Bioadhesive Testosterone Preparations. A buccal tablet is applied to the gum above the upper incisors, providing a sustained release of T via the buccal mucosa into the circulation. It is effective in increasing serum T levels, but data on improvement of hypogonadal symptoms are lacking.[63,69]

Transnasal Testosterone Preparations. Via a metered-dose pump applicator, nasal T gel can be applied into the nostrils. With the recommended dose of 11 mg, 90% of patients reached T levels in the normal range. In open-labeled trials, erectile function, body composition, and BMD improved, but placebo-controlled data or trials comparing the nasal gel with more commonly used formulations are lacking.[70]

Androgens Other than Testosterone

Dehydroepiandrosterone. Dehydroepiandrosterone (DHEA) is a weak androgen and a precursor of T. A few placebo-controlled trials have shown no convincing evidence that DHEA improves hypogonadal symptoms, and it is not recommended as an alternative treatment in men with androgen deficiency.[71]

Dihydrotestosterone Gel and Mesterolone. A transdermal gel containing DHT (Androstanolone) or an oral preparation containing a synthetic androgen derived from DHT (Mesterolone) are available in some countries. These preparations can only exert androgenic effects, as they cannot be aromatized to E2. For this reason, they are not indicated to treat hypogonadal men.

Efficacy

It is generally accepted that restoration of circulating T concentrations in hypogonadal men to the midphysiological range will invariably ensure an efficacious and sustained clinical response (Key Points: Treatment). Indeed, this has been the longstanding strategy for regulatory approval of new T products, which requires only this pharmacokinetic target to be satisfied, without the need for demonstrating clinical efficacy outcomes. TRT is highly effective in inducing secondary sexual characteristics in younger patients with incomplete sexual development due to organic hypogonadism (Fig. 106.2). In adult men with confirmed hypogonadism, the most consistent clinical benefit of TRT is the improvement in libido, erectile function, sexual activity, and sexual satisfaction.[72] Lean mass (and muscle strength in most studies) increases and fat mass decreases consistently in response to TRT. However, the effects of TRT on mood and well-being are less predictable.

In older men with low T, there is no convincing evidence that TRT improves depressive symptoms or fatigue, nor does it have a positive effect on cognitive function or memory.[73] Despite the increase in lean mass in response to TRT in older men with low T, placebo-controlled trials showed no or only minimal improvements in walking distance or gait speed.[73] There is some evidence that TRT can improve insulin sensitivity in hypogonadal men with type 2 diabetes or the metabolic syndrome, but any benefit on glycemic control is unconvincing.[74] TRT also has a positive effect on vertebral and femoral BMD. However, there are no data indicating that TRT reduces the risk of osteoporotic fractures, and TRT on its own is not approved for treating osteoporosis. In hypogonadal men with a high fracture risk, TRT alone is not sufficient, and a bone-specific osteoporosis treatment should be added.

Contraindications and Adverse Events

Minor adverse events related to TRT include oily skin, acne, and breast tenderness. Formulation-specific adverse effects are described in Table 106.5. Contraindications for TRT are summarized in Box 106.2.

Exogenous T suppresses spermatogenesis, so TRT is contraindicated in men planning fertility in the near future. Alternative treatment in men with secondary hypogonadism seeking fertility is discussed below.

BOX 106.2 Contraindications for Testosterone Replacement Therapy

Desire for fertility in the near future
Untreated and treated breast cancer
Untreated, locally advanced or metastatic prostate cancer
Unevaluated palpable prostate nodule
Unevaluated PSA >4 ng/mL (>3 ng/mL in men with high risk for prostate cancer, e.g., Black Americans or men with affected first-degree relatives)
Severe lower urinary tract symptoms (IPSS >19)
Hematocrit >48%–50%
Thrombophilia
Severe congestive heart failure
Recent myocardial infarction or stroke
Untreated sleep apnea

PSA, Prostate-specific antigen; *IPSS*, international prostate symptom score.

TRT is contraindicated in men with breast cancer and men with untreated, locally advanced or metastatic prostate cancer, both being sex steroid-responsive malignancies. Prostate-specific antigen (PSA) levels and prostate volume can increase within the physiological range shortly after TRT is started in hypogonadal men. There is currently no evidence that TRT increases the risk of prostate cancer, but the data are based on short-term studies with duration up to 36 months only.[75] Because T can promote growth of an occult preexisting prostate tumor, current guidelines recommend screening for undiagnosed prostate cancer prior to starting TRT in men over 40 years of age via digital rectal examination and measurement of PSA. If PSA is greater than 4 ng/mL (>3 ng/mL in men with high risk for prostate cancer, e.g., Black Americans or men with affected first-degree relative) or a palpable prostate nodule is present, further evaluation by a urologist is required. It is also recommended to monitor PSA and prostate volume 3 and 12 months after TRT is started. Afterwards, the local guidelines for prostate cancer screening for the general population should be followed.

In men with a history of low-grade prostate cancer who have been treated with a radical prostatectomy and have undetectable PSA levels for at least 2 years, TRT may be considered in those with low T levels and severe hypogonadal symptoms. However, initiating TRT in men with a history of prostate cancer remains controversial, and there is currently insufficient evidence to support a generally accepted recommendation.[1,76] The risks and benefits of TRT should be discussed with the patient, and PSA levels should be monitored regularly if TRT is started in this group.

Severe LUTS (International Prostate Symptom Score [IPSS] ≥19) associated with benign prostatic hyperplasia is a relative contraindication, but modest LUTS (IPSS <19) is not, because there is no deterioration from TRT.[1,2]

T stimulates erythropoiesis, and TRT is contraindicated in men with a high hematocrit (>48%–50%). Erythrocytosis (hematocrit >54%) is a frequent adverse event in men using TRT. It occurs more frequently in older patients and with intramuscular injections, and is dose-dependent. TRT should be discontinued until hematocrit is normal again, in some cases after venesection.

TRT can increase the risk of venous thromboembolism in men with thrombophilia (often undiagnosed). Personal and family history of thromboembolic events and risk factors should be sought before starting TRT. The frequency of neuroocclusive events in men who developed TRT-induced erythrocytosis is however low, and the number of venous thromboembolic events in randomized controlled trials (RCTs) was too low to draw conclusions about the risk.[1,72]

Untreated sleep apnea, severe heart failure, recent myocardial infarction, and stroke are also considered contraindications for TRT. There has been concern that TRT increases cardiovascular disease risk. This is mainly based on data from retrospective studies, in which there was no information available about hypogonadal symptoms, the underlying condition, and T levels. Available RCTs on TRT with duration of only 6 to 36 months have not been designed or were not sufficiently powered to detect a difference in major adverse cardiovascular events. However, most metaanalyses show no association between TRT and cardiovascular events in men with an established diagnosis of hypogonadism.[75] Following the directive of the FDA, an industry-sponsored multicenter RCT has recently been launched to investigate the cardiovascular disease risk of TRT in older men in the United States.

Monitoring of Treatment

After TRT is started, improvement of hypogonadal signs and symptoms is expected within 3 to 6 months, which should be reviewed clinically. It is generally recommended to measure T 3 months after TRT is started and to aim for serum T concentrations in the mid-normal range for healthy young men.[1,2] The timing to measure serum T levels depends on the formulation used. For intramuscular injections of testosterone cypionate or enanthate, the interval between injections can be optimized by measuring serum T just before the next injection, which should be at the lower limit of the reference range.[77] When using a transdermal T gel, serum T levels should be measured 4 to 12 hours after application. After 2 to 4 weeks of daily usage, the dose can be adjusted to obtain T concentrations in the normal range. Patients maintained on long-term TRT should be clinically evaluated at least annually, including review of therapeutic goals and measuring serum T and hematocrit (Key Points: Treatment). Patients receiving the newest oral formulations of testosterone undecanoate should have T sampled 4 to 7 hours after taking the morning capsule(s).

GONADOTROPIN INDUCTION OF SPERMATOGENESIS AND FERTILITY

Besides being candidates for TRT, gonadotropin-deficient patients with secondary hypogonadism can benefit from treatments that, by activating or reactivating the dormant testis, stimulate endogenous T secretion as well as spermatogenesis. This option is not feasible in primary hypogonadal patients, where the pathological testes will not respond to exogenous gonadotropin stimulation (Key Points: Treatment).

Indications

Gonadotropin treatment may be considered more physiological than TRT in secondary hypogonadism, but it is more burdensome, having to be administered by subcutaneous or intramuscular injections two or three times a week. In addition, it is more expensive than TRT. For these reasons, although potentially suitable for all patient with secondary hypogonadism, its use is generally limited to patients who require fertility.

Gonadotropin Treatment

Preparations with Luteinizing Hormone-Like Action. LH-like preparations can stimulate Leydig cells (Table 106.6). Recombinant LH is expensive, has a very short half-life, and has not been extensively tested or approved for the use in men. hCG binds the LH receptor with the same affinity as native LH but has a much longer half-life. hCG extracted from urine of pregnant women is the most frequently used treatment for Leydig cell stimulation, being administered subcutaneously or intramuscularly two or three times a week.

TABLE 106.6 Gonadotropin and GnRH treatment for Hypogonadotropic Hypogonadism to induce fertility in adulthood

	Dose	Regimen
LH-like preparations		
rhLH	No data available	• Start LH-like preparations alone • Start LH-like and FSH-like preparations together
hCG	1000–2000 IU Two to three times weekly	
rhCG	No data available	
FSH-like preparations		
hMG	75–225 IU Two to three times weekly	• Add FSH-like preparations after 6 months of LH-like therapy with sperm concentration <10 million/mL • Increase FSH-like therapy (in combination with LH-like preparations) after 6 months of lower dosage with sperm concentration <20 million/mL • Start FSH-like preparations together with LH-like preparations and increase FSH after 6 months of lower dosage with sperm concentration <20 million/mL
hpFSH	75–225 IU Two to three times weekly	
rhFSH	75–225 IU Two to three times weekly	
Corifollitropin alfa	150 μg every other week	
GnRH		
Native GnRH	100–400 ng/kg every 90–120 min	GnRH only until outcome is achieved

GnRH, Gonadotropin-releasing hormone; *hMG*, human menotropin; *hpFSH*, highly purified follicle stimulating hormone; *rhFSH*, recombinant human follicle-stimulating hormone; *rhLH*, recombinant human luteinizing hormone; *hCG*, human chorionic gonadotropin; *rhCG*, recombinant human chorionic gonadotropin.

Preparations with Follicle-Stimulating Hormone-Like Action. FSH action can be replicated by human menopausal gonadotropin (hMG) and highly purified FSH (hpFSH), or by synthetic recombinant human FSH (rhFSH) (Table 106.6). hMG is a mixture of gonadotropins extracted from human urine with both FSH- and LH-like action, while predominant or exclusive FSH stimulation is provided by hpFSH and rhFSH, respectively. These selective preparations are more expensive; they are specifically designed for ovulation induction, which requires a precise dose/sequence of FSH and LH stimulation. This is not the case for males, and at present there is no evidence to indicate superiority of hpFSH and rhFSH over hMG in the induction of spermatogenesis.[35] FSH preparations are administered by subcutaneous or intramuscular injections two to three times weekly. To overcome the multiple injection issue, recently, corifollitropin alfa has been evaluated for the use in men (Table 106.6). Corifollitropin alfa is a recombinant gonadotropin, made of the α-subunit of human FSH and a hybrid subunit composed of the β-subunit of human FSH and the C-terminal of the β-subunit of hCG, with similar bioactivity to rhFSH. Corifollitropin alfa has longer circulating half-life and allows administration every other week, a characteristic that may improve compliance in prolonged treatment required in the induction of spermatogenesis.

Treatment Regimens. Adult patients with secondary hypogonadism can start gonadotropins when they are seeking fertility. There is no consensus on the best dose and regimen for stimulation of spermatogenesis in adult men (Table 106.6). With a view to cost-effectiveness, it is generally advised to start with hCG 1000 to 2000 IU two or three times weekly. If sperm concentration remains below 10 million/mL and conception is not achieved within 6 months, FSH/hMG is added with a starting dose of 75 IU alternate days or three times weekly.[78] After a further 6 months of treatment, if conception does not occur and sperm concentration is below 20 million/mL, FSH/hMG may be titrated up to 150 IU.[78] It should be noted that, if costs are not a concern, combined hCG and FSH/hMG treatment may be started from the beginning.[78]

It should be emphasized that promotion of spermatogenesis requires relatively prolonged treatment, because one complete cycle of germ cell differentiation takes 3 months (see Chapter 111). Usually, at least 6 months (two cycles of spermatogenesis) of therapy are required to produce clinically significant results.

Outcomes

Semen Parameters. A meta-analysis of studies considering semen outcomes in adult azoospermic secondary hypogonadal men treated with gonadotropins has shown that sperm in the ejaculate is obtained on average in 75% of men, with a sperm concentration of approximately 6 million/mL.[35] Larger baseline testis volume has been consistently found to be a predictor of earlier achievement of sperm output with gonadotropin therapy.[79] Moreover, better results were obtained in men with postpubertal-onset secondary hypogonadism and in those with lower endogenous pretreatment LH and FSH levels.[35] hCG alone could induce sperm output in almost 50% of cases, but sperm concentration remained below 1 million/mL, whereas combined FSH/hMG and hCG treatment is associated with sperm appearance in the ejaculate in 80% of previously azoospermic men, achieving an average sperm concentration of 12 million/mL.[35] Different FSH-like preparations (hMG, hpFSH, rhFSH) produced similar outcomes.[35] A potential detrimental role of previous TRT (usually for induction of secondary sexual development) on semen quality in response to gonadotropin treatment in adulthood was not confirmed.[35] However, it should be noted that this conclusion was based on cumulative data of final outcomes irrespective of different treatment durations. When considering the time needed to achieve sperm output in response to gonadotropin therapy, previous TRT may be a factor in delaying sperm output (40%–60% longer time than TRT-naïve subjects) and attaining peak sperm count (16 months later than TRT-naïve subjects).[79,80] This possible delay in achieving fertility can be a significant issue in light of the trend of increasing age at which couples seek fertility.

Fertility (Also See Chapters 112 and 115). Assessing fertility outcomes in secondary hypogonadal men receiving gonadotropin therapy is challenging, because the fecundity of the female partner plays a critical role. It should be noted that, in secondary hypogonadism without adverse testicular factors (e.g., cryptorchidism), semen quality is usually good despite lower sperm concentrations, so that most patients are nevertheless able to achieve spontaneous pregnancy.[35,78] In the aforementioned meta-analysis, spontaneous pregnancy was obtained on average by 50% of subjects, but it should be noted that not all men included in the meta-analyzed studies were seeking paternity, so fertility rate may be even higher.[35] Fertility from gonadotropin treatment is less likely in men with cryptorchidism or in those having a partner with adverse fertility factors. Unlike sperm output, pretreatment testis volume does not affect pregnancy outcome.[80] In line with sperm output, previous TRT does not affect fertility rate, although it has been associated with a delay in achieving pregnancy.[80]

Adverse Effects. Gonadotropin treatment is generally well tolerated and safe. The side effect most frequently reported is gynecomastia (9% of treated adult men), due to hCG/LH-mediated stimulation of E2 production.[75] The highest incidence was reported with the use of hMG, which has both FSH- and LH-like action.[75] Acne is the second most reported side effect (7%), followed by local injection site reaction and weight gain (both 5%).[75]

Gonadotropin-Releasing Hormone Treatment

Pulsatile GnRH treatment is an alternative to gonadotropin therapy in secondary hypogonadal patients with intact pituitary function. It is administered by subcutaneous pumps that release pulses of 100 to 400 ng/kg of GnRH every 90 to 120 minutes, thus mimicking the physiological hypothalamic pulsatile release of GnRH (Table 106.6) and avoiding downregulation of the GnRH receptors. The need to wear a pump makes this treatment expensive and burdensome, limiting its routine clinical application. In young adults with secondary hypogonadism treated with GnRH, spermatozoa in the ejaculate was obtained on average in 75% of azoospermic subjects, with a mean sperm concentration of 4.3 million/mL. However, direct head-to-head comparison between GnRH and gonadotropin treatment in a limited number of studies suggested a similar efficacy in improving sperm count, although shorter time was required with GnRH, which also produced greater testicular size.[81-83]

FUTURE DIRECTIONS

Functional hypogonadism:
- increase diagnostic awareness and promote its reversibility if possible
- conduct large-scale RCTs to determine long-term efficacy and safety of TRT

Klinefelter syndrome:
- improve diagnosis in “subclinical” cases
- establish postnatal screening programs
- establish multidisciplinary care to:
  - preserve/improve fertility potential
  - early intervention for neurocognitive and behavioral problems
  - promote general health
- Improve the accuracy and standardization of T and free T measurements and harmonize international reference ranges.
- promote general health

Testosterone Deficiency: Aging and Chronic Disease

Peter J. Snyder

OUTLINE

Aging, 1804
Acute and Chronic Disease, 1807
Medications, 1808

Serum testosterone concentrations decrease not only in diseases of the hypothalamus, pituitary, and testes, but also in association with aging, systemic diseases, and certain medications.

AGING

KEY POINTS

- With aging, a man's serum testosterone concentration decreases slightly, but because the sex hormone–binding globulin concentration increases, the free testosterone decreases more.

Decrease in Testosterone as Men Age. Serum testosterone concentrations decrease with increasing age. In contrast to the decrease in estradiol in women at menopause, which usually occurs over 2 years or less and to very low levels, the decrease in testosterone in men is gradual, over many decades, and to a modest degree. Also in contrast to menopause, which is the result of primary hypogonadism, the fall in testosterone appears to be caused by both primary and secondary hypogonadism.

Total Testosterone. Several cross-sectional studies demonstrated small decreases in serum concentrations of total testosterone from age 20 to 80 years. The European Male Aging Study evaluated 3220 men aged 40 to 79 years old and found that the serum total testosterone concentration fell only 0.04% per year (Fig. 107.1).[1] A study in Australia of 10,904 serum samples from community-dwelling men aged 35 to 99 years showed a gradual decline in testosterone concentration until age 80 years and a steeper decrease thereafter.[2] A study that combined samples from four other studies of 9054 community-dwelling men aged 19 to 99 years showed that the median serum testosterone concentration in men decreased only from 507 ng/dL in men 19 to 39 years of age to 446 ng/dL in men 80 to 99 years of age, but the fifth percentile decreased from 273 to 203 ng/dL, and the 2.5th percentile decreased from 229 to 119 ng/dL.[3]

Several longitudinal studies also demonstrated decreases in serum total testosterone concentrations, and to a somewhat greater degree than the cross-sectional studies. In the Baltimore Longitudinal Study on Aging, 890 men demonstrated a decrease in serum total testosterone concentration of approximately 519 ng/dL at age 30 years to 346 ng/dL at age 80 years.[4] In the Massachusetts Male Aging Study, of 1709 men evaluated initially, 1156 were evaluated a second time, an average of 8 years later, and 853 a third time, an average of 7 years after the second time.[5] Regression modeling estimated a decrease in serum total testosterone concentration of 14.5% per decade of aging.

The decrease in serum testosterone concentration with aging occurs particularly in the early morning. Men 20 to 40 years old exhibit a distinct diurnal pattern of serum testosterone, with prominent peak values occurring at approximately 8:00 a.m. and nadir values at 8:00 p.m., whereas men 60 to 80 years old exhibit a dampened early morning peak.[6]

Sex Hormone–Binding Globulin and Free Testosterone. Sex hormone–binding globulin (SHBG) increased with increasing age in the European Male Aging Study; the increase was approximately 50% from the early 40s to late 70s.[1] As a consequence of the increase in SHBG with aging, the free testosterone decreases to a greater degree than the total.[1] The concentrations in men 75 to 79 years old were about 30% lower than those in men 40 to 44 years old.

Luteinizing Hormone. The serum concentration of luteinizing hormone (LH) increases with increasing age,[1] but not as much as one would expect from the decrease in testosterone if the cause of the hypogonadism was exclusively as a result of Leydig cell damage, suggesting that the fall in testosterone is caused by a combination of primary and secondary hypogonadism.

Summary of the Changes in Testosterone with Aging. As men age, their serum total testosterone concentrations fall modestly, but because the concentrations of SHBG increase with increasing age, the fall in free testosterone is greater.

Effects of Testosterone Treatment of Older Men With Low Testosterone

KEY POINTS

- Testosterone replacement in older men with low testosterone improves all aspects of sexual function and increases walking distance, erythropoiesis, and bone mineral density, but does not improve vitality or cognitive function. This treatment also increases coronary artery plaque volume.

The parallels between many of the consequences of severely low testosterone and many of the consequences of normal aging in men—decreased sexual function, decreased muscle mass and strength, decreased bone mineral density, and decreased hemoglobin—suggest that decreasing testosterone might be one cause of these consequences

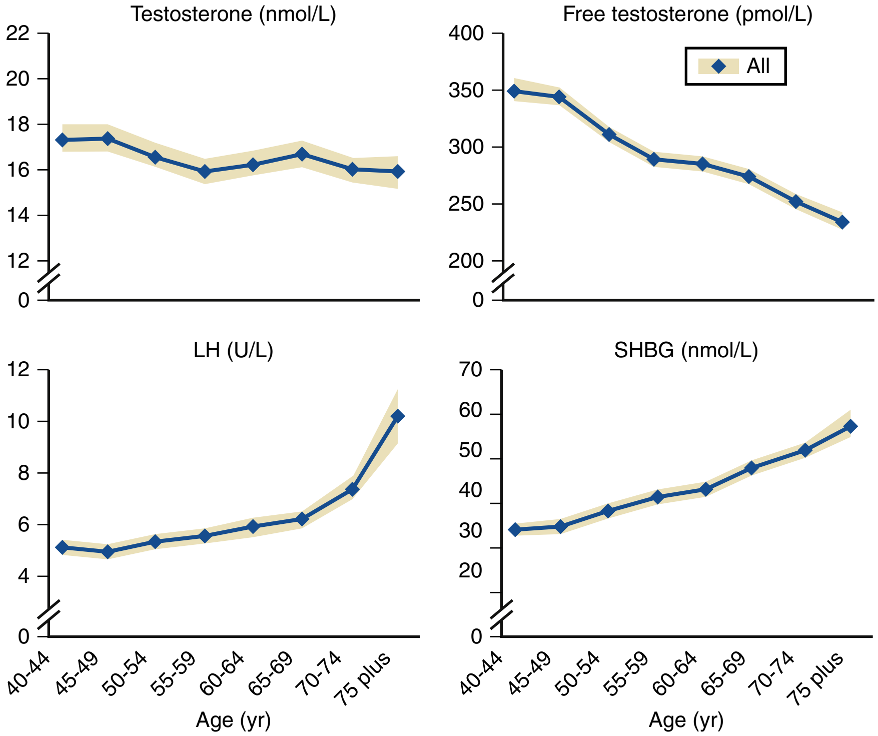

Fig. 107.1 Mean (95% confidence interval) serum concentrations of testosterone, free testosterone, luteinizing hormone (*LH*), and sex hormone–binding globulin (*SHBG*) with aging in 3220 men in the European Male Aging Study. (From Wu FC, Tajar A, Pye SR, et al. Hypothalamic-pituitary-testicular axis disruptions in older men are differentially linked to age and modifiable risk factors: the European Male Aging Study. *J Clin Endocrinol Metabol.* 2008;93:2737–2745.)

in older men. Small clinical trials of testosterone treatment of older men in the 1990s suggested possible improvement in some of these parameters, but a committee of the National Academy of Medicine was not convinced. In 2004, the committee recommended that a coordinated set of clinical trials be conducted to determine if testosterone treatment of older men with low testosterone would have any beneficial effect.[7] The Testosterone Trials were designed to implement this recommendation, and the results were reported from 2010 to 2020. A few other trials were conducted during the same period.[8-10]

The Testosterone Trials. The Testosterone Trials were a coordinated group of seven trials (Sexual Function, Physical Function, Vitality, Cognitive Function, Anemia, Bone, and Cardiovascular) conducted to determine if raising the serum testosterone levels in older men with low testosterone would have any benefit.[11] More than 50,000 men were screened to find 790 men who met all of the entry criteria and enrolled.[12] Only 15% of men screened met the enrollment criterion of a serum testosterone concentration of less than 275 ng/dL on two occasions, indicating that, even in elderly men, a low testosterone level is not common. Their mean age was 72 years, and their mean body mass index was 31 kg/m^2; 89% were Caucasian.[13] Enrollees were allocated to treatment with a testosterone gel or placebo; the dose was adjusted to maintain the serum testosterone concentration within the normal range for 1 year. Participants were evaluated for efficacy periodically during the year of treatment.

A total of 705 men (89%) completed the 1-year course of treatment and evaluations.[13] During the year of treatment, the serum testosterone concentrations increased from a median of 234 ng/dL at baseline to the mid-500s during treatment. Serum free testosterone and estradiol also increased to midnormal during treatment.

Beneficial Effects of Testosterone Treatment. Testosterone treatment of men in the Testosterone Trials improved sexual function, walking, mood, hemoglobin, bone density, and strength, each to variable degrees.[14]

Sexual Function. Testosterone treatment, compared with placebo, improved several aspects of sexual function, especially sexual activity—from flirting to intercourse—and libido and, to a lesser extent, erectile function (Fig. 107.2).[13,15] The increases in sexual function and libido, but not erectile function, were significantly associated with the increases in total and free testosterone and estradiol. Testosterone treatment had similar effects in 751 middle-aged men who had low testosterone concentrations.[10]

Physical Function. Testosterone treatment was associated with a small improvement in walking—the distance walked in 6 minutes—in all men in the Testosterone Trials (Fig. 107.3) and also in their perception that their walking had improved.[13,16] These increases were associated with increases in free and total testosterone and hemoglobin. In two smaller trials, testosterone did not improve walking, although it did improve strength.[8,9]

Mood. Testosterone treatment was associated with small but significant improvements in mood, both an increase in positive mood and a decrease in negative mood, as measured by the Positive and Negative Assessment Scales.[13] Treatment was also associated with a small but significant decrease in depressive symptoms, as measured by the Patient Health Questionnaire-9.

Erythropoiesis. In the 126 men in the Testosterone Trials who were anemic at baseline, testosterone increased hemoglobin more than placebo, both in men who were classified as having unexplained anemia (Fig. 107.4) and in men who had anemia of known causes, such as iron deficiency.[17] The average increase in hemoglobin was approximately 1.0 g/dL in both groups.

Bone Mineral Density. A total of 211 men in the Testosterone Trials had measurements of volumetric bone mineral density (vBMD) by

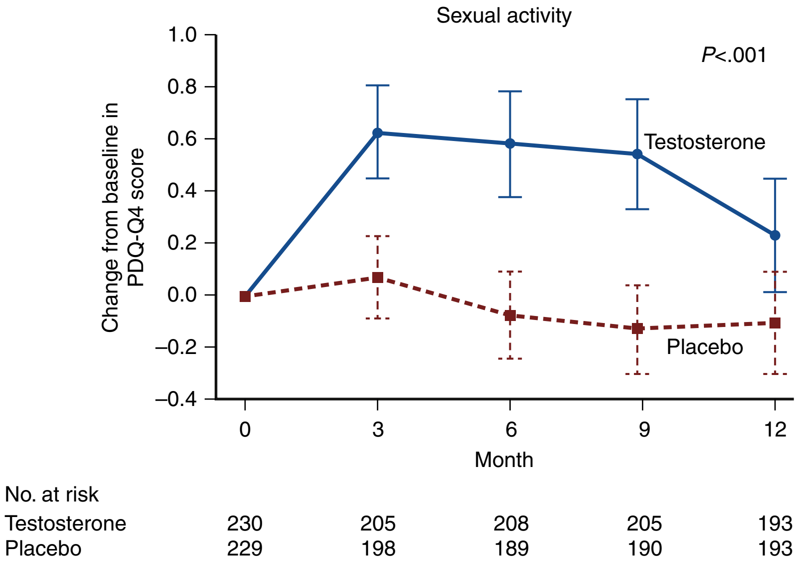

Fig. 107.2 **Mean (95% confidence interval) change in sexual activity when older men with low testosterone were treated with testosterone or placebo for 1 year. Sexual activity was assessed by question 4 of the Patient Daily Questionnaire (PDQ-Q4).** (From Snyder PJ, Bhasin S, Cunningham GR, et al. Effects of testosterone treatment in older men. *NEJM.* 2016;374:611–624.)

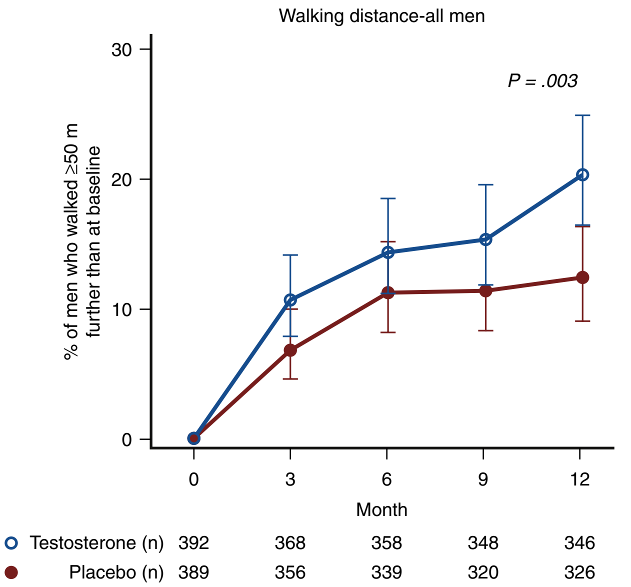

Fig. 107.3 **The mean (95% confidence interval) change in walking distance when older men with low testosterone were treated with testosterone or placebo for 1 year.** (From Snyder PJ, Bhasin S, Cunningham GR, et al. Lessons from the testosterone trials. *Endocr Rev.* 2018;39:369–386.)

quantitative computed tomography (QCT) at baseline and again after 1 year of testosterone treatment.[18] Bone strength was estimated from QCT data by finite element analysis. Testosterone treatment increased vBMD of trabecular bone in the lumbar spine 6.8% more than placebo (Fig. 107.5); the effects on whole bone in the spine and trabecular and whole bone in the hip were less but still significant. Estimated bone strength increased similarly.

Lack of Beneficial Effects. Prior studies of testosterone had suggested that testosterone treatment of older men with low testosterone might have several other beneficial effects, including on vitality, cognition, lipids, and glucose metabolism, but testosterone treatment of the 790 men in the Testosterone Trials had no effect on any of these parameters.

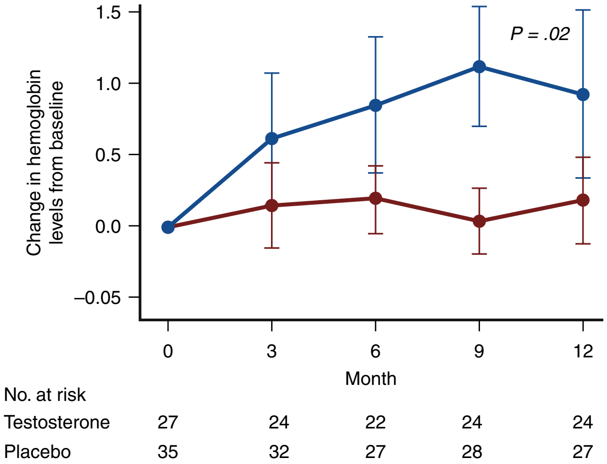

Fig. 107.4 **The mean (95% confidence interval) change in hemoglobin (g/dL) when older men with low testosterone and unexplained anemia were treated with testosterone *(dark green)* or placebo *(orange)* for 1 year.** (From Snyder PJ, Bhasin S, Cunningham GR, et al. Lessons from the testosterone trials. *Endocr Rev.* 2018;39:369–386.)

Vitality. The effect of testosterone on vitality, as measured by the Functional Assessment of Chronic Illness Therapy Fatigue scale, was very small and of borderline significance for all men in the Testosterone Trials.[13]

Cognition. Testosterone treatment had no effect on any aspect of cognition, including delayed or immediate paragraph recall, visual memory, spatial ability, and executive function, in the 493 men in the Testosterone Trials who had age-associated memory impairment.[19]

Lipids and Glucose. Testosterone treatment of all 788 men in the Testosterone Trials was associated with very small changes in total cholesterol, high density lipoprotein cholesterol, and low density lipoprotein cholesterol, none of sufficient magnitude to suggest clinical significance.[20] Treatment was also associated with small decreases in insulin and homeostatic model assessment–insulin resistance but no changes in fasting glucose or hemoglobin A1c concentrations.

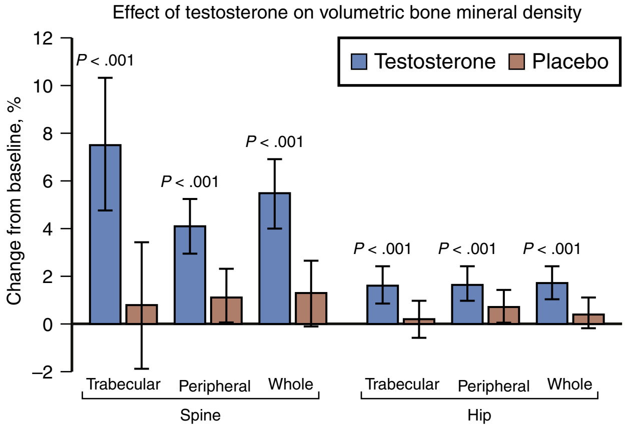

Fig. 107.5 The mean (95% confidence interval) percent change in volumetric bone mineral density of trabecular, peripheral, and whole bone of the spine and hip as determined by quantitative computed tomography when older men with low testosterone were treated with testosterone or placebo for 1 year. (From Snyder PJ, Kopperdahl DL, Stephens-Shields AJ, et al. Effect of testosterone treatment on volumetric bone density and strength in older men with low testosterone: a controlled clinical trial. *JAMA Intern Med.* 2017;177:471–479.)

Risks of Testosterone Treatment. Several potential risks of treating older men with testosterone have been proposed. These include stimulating the growth of dormant prostate cancer, worsening benign prostatic hyperplasia, and causing adverse cardiovascular events.

Prostate Cancer. The possibility that testosterone treatment of older men may stimulate the growth of previously dormant prostate cancer has been raised, because the majority of older men harbor silent prostate cancer, and because metastatic prostate cancer can be ameliorated for a period by drastic reduction of the serum testosterone concentration. In the Testosterone Trials, only one man, who was in the testosterone arm, was diagnosed with prostate cancer during the year of treatment.[13] In a metaanalysis of 51 randomized trials of testosterone treatment designed to evaluate a variety of primary outcomes, testosterone treatment was not associated with an increased incidence of prostate cancer.[21] The numbers of men were too small, and the duration of the observations in these studies were too short, however, to draw conclusions about this risk.

Benign Prostatic Hyperplasia. In the Testosterone Trials, all 788 participants were evaluated for lower urinary tract symptoms using the International Prostate Symptom Score. The number of men whose score increased to a level indicating moderately severe symptoms was similar in the men treated with testosterone and the men treated with placebo.[13] In a metaanalysis of 1779 men in four clinical trials, testosterone had no significant effect on lower urinary tract symptoms.[22] The numbers of men and the duration of treatments were too short to draw conclusions about this risk.

Adverse Cardiovascular Events. Several studies suggest the possibility that testosterone treatment of older men with low testosterone may increase the risk of cardiovascular adverse events. Two retrospective cohort studies reported that slightly more men who received testosterone had major adverse cardiovascular events than men who did not.[23,24] A clinical trial of testosterone in men with mobility limitations was stopped early because more men treated with testosterone reported cardiovascular events than men treated with placebo.[25] In a subgroup of 170 men in the Testosterone Trials, testosterone treatment increased coronary artery plaque volume, as determined by computed tomography angiography, by 40 mm^3 in 1 year, compared with 4 mm^3 in the placebo treatment group (Fig. 107.6).[26]

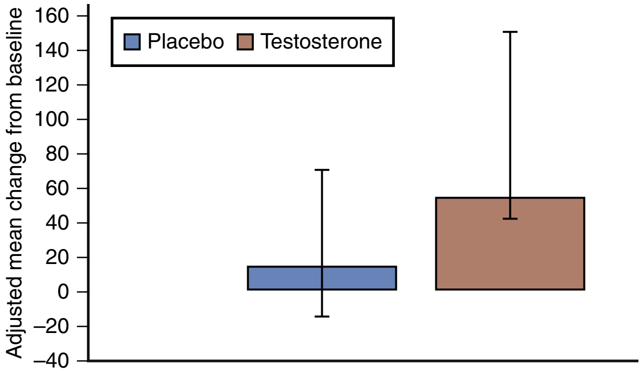

Fig. 107.6 The least mean square (95% confidence interval) percent change in coronary artery plaque volume as determined by computed tomographic angiography when older men with low testosterone were treated with testosterone or placebo for 1 year. (Adapted from Roy CN, Snyder PJ, Stephens-Shields AJ, et al. Association of Testosterone Levels With Anemia in Older Men: A Controlled Clinical Trial. *JAMA internal medicine.* 2017; 177: 480–490. 2017/02/28. DOI: 10.1001/jamainternmed.2016.9540.)

Other studies, however, do not confirm this risk. Another retrospective cohort study showed no increased cardiovascular risk of testosterone.[27] A second clinical trial of testosterone in older men with mobility limitations reported few adverse cardiovascular events.[8] In a clinical trial of 308 older men, testosterone treatment for 3 years did not increase carotid intima media thickness more than placebo.[28] In the Testosterone Trials, the number of major adverse cardiovascular events was similar in the testosterone-treated and placebo-treated men.[13] Although the Testosterone Trials was the largest study of testosterone treatment, it was not nearly large enough and long enough to draw conclusions about cardiovascular risk.

Summary of the Effects of Testosterone Treatment of Older Men with Low Testosterone. Testosterone treatment of older men who have low testosterone has clear benefits—on sexual function, walking, mood, erythropoiesis, and bone density—but the risks are not yet known.

ACUTE AND CHRONIC DISEASE

KEY POINTS

- Several diseases are associated with low testosterone. Improvement of those conditions usually leads to increases in testosterone.

Many acute and chronic diseases cause hypogonadism. The specific mechanisms by which these conditions cause hypogonadism are not known, but most cause secondary hypogonadism, and a few cause a combination of primary and secondary hypogonadism. In many cases, the hypogonadism is reversible; if the disease remits or can be successfully treated, the hypogonadism is reversed.

Critical Illness. Two prospective studies document that critical illness of any kind causes secondary hypogonadism. One study found that 35 men who had trauma, surgery, or myocardial infarction experienced declines in serum testosterone concentrations of approximately 200 ng/dL, accompanied by decreases in LH concentrations, within the first few days after the event.[29] Another study of 59 men found similar decreases in testosterone and LH in response to critical illness and also found that the fall in testosterone was greater the more severe the illness.[30] Serum testosterone increased to normal as the patients recovered from the illness.

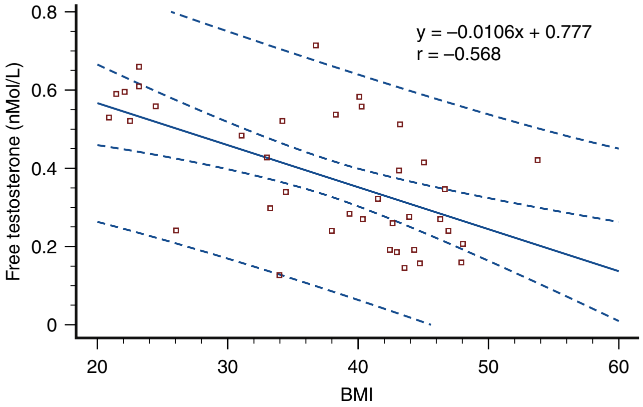

Fig. 107.7 Correlation of free testosterone with body mass index *(BMI)*. (From Vermeulen A, Kaufman JM, Deslypere JP, et al. Attenuated luteinizing hormone (LH) pulse amplitude but normal LH pulse frequency, and its relation to plasma androgens in hypogonadism of obese men. *J Clin Endocrinol Metabol*. 1993;76:1140–1146.)

Anorexia Nervosa. Males who have anorexia nervosa have hypogonadotropic hypogonadism, as do females. In a study of 15 adolescent boys, the mean testosterone concentration was 187 ng/dL, compared with 414 ng/dL in 15 age-matched controls.[31]

Diabetes Mellitus. Many studies have explored testosterone levels in men with diabetes mellitus. Overall, testosterone appears to be lower in diabetics than nondiabetics, but only to a modest degree, and LH is not elevated, indicating that the hypogonadism is secondary. In one metaanalysis, the serum testosterone concentration was 77 ng/dL lower in the diabetic men.[32] In another metaanalysis, testosterone was 86 ng/dL lower in the diabetic than the nondiabetic men.[33] Many studies have also explored the possibility that testosterone treatment would improve glucose control in men who have diabetes. A metaanalysis showed that testosterone treatment of diabetic men with low testosterone resulted in no overall improvement in hemoglobin A1c levels.[33]

Obesity. Obesity causes low serum testosterone by two mechanisms. Men who are obese have lower serum levels of SHBG than men of normal weight, which results in a low total testosterone.[34,35] Men who are obese also have secondary hypogonadism, as determined by low levels of free testosterone; the degree of hypogonadism is proportional to the degree of obesity (Fig. 107.7).[35-37] The hypogonadism is secondary because serum LH levels are not elevated because of decreased LH pulse frequency.[37]

Sleep Apnea. Although some studies report low serum testosterone concentrations in men who have sleep apnea,[38,39] a metaanalysis of five observational studies and two clinical trials comprising a total of 232 men showed no effect of continuous positive airway pressure on serum testosterone concentrations.[40] This finding suggests that the low testosterone in these men may be because of obesity.

Human Immunodeficiency Virus Infection. Before the availability of antiretroviral drugs, human immunodeficiency virus (HIV) infection was sometimes associated with hypogonadism,[41] mostly secondary, especially when accompanied by muscle wasting. Even then, it was not common, as shown by a study of 213 HIV-infected men.[42] Before antiretroviral treatment, the mean serum free testosterone concentration was 92 pg/mL, and only 6% of patients had subnormal values (<50 pg/mL). Antiretroviral treatment of these men for 64 weeks increased the serum free testosterone concentration by 15 pg/mL. In a study of men participating in the Multicenter AIDS Cohort Study Cardiovascular Substudy, the mean total serum testosterone concentration in 364 HIV-infected men was similar to that in 166 uninfected men (629 ng/dL vs. 650 ng/dL, $P = .43$), but the SHBG concentration was slightly higher (52.6 nmol/L vs. 47.3 nmol/L, $P = .02$) and the calculated free testosterone concentration slightly lower (100.2 pg/mL vs. 107.3 pg/mL, $P = .005$) in the HIV-infected men (Fig. 107.8).[43]

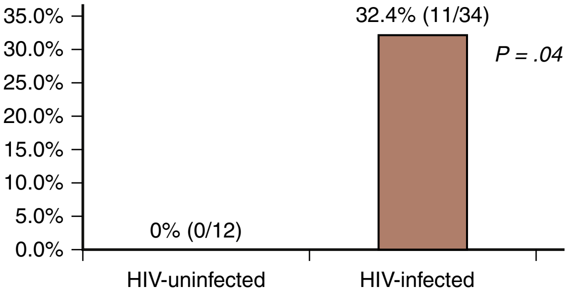

Fig. 107.8 Percentage of men by human immunodeficiency virus *(HIV)* status who had normal testosterone but subnormal free testosterone. (From Monroe AK, Dobs AS, Palella FJ, et al. Morning free and total testosterone in HIV-infected men: implications for the assessment of hypogonadism. *AIDS Res Ther*. 2014;11:6.)

Cirrhosis. Cirrhosis of the liver may be associated with hypogonadism, which may be primary, indicated by elevated serum concentrations of LH and follicle-stimulating hormone (FSH) and by subnormal testosterone responses to administration of human chorionic gonadotropin.[44] Other patients with hypogonadism associated with cirrhosis do not have elevated gonadotropin concentrations. An additional feature of this hypogonadism is elevated serum estradiol concentrations, which cause gynecomastia and elevated serum SHBG concentrations. Hepatic transplantation corrects the hypogonadism.[45]

Chronic Kidney Disease. Severe chronic kidney disease causes hypogonadism primarily by testicular damage. In a study of 35 men whose creatinine clearance rates were less than 4 mL/min/1.7 m², low testosterone was accompanied by elevations of FSH and LH and severe spermatogenic damage as determined by biopsy.[46] The hypogonadism is often corrected following renal transplantation, as illustrated by a study of 97 men with end-stage renal disease.[47] Before renal transplantation, 40% were hypogonadal, but 1 year afterwards, only 18% were. Recovery from hypogonadism was greater in men less than 50 years of age than in those over 50 years of age.

MEDICATIONS

KEY POINTS

- Several medications suppress gonadotropin secretion and thereby cause hypogonadism. Discontinuation of the medication allows recovery of the pituitary-testicular axis, but the time needed for recovery may be prolonged.

Several types of medications cause hypogonadism, some by suppressing gonadotropin secretion and some by damaging the testes.

Gonadotropin-Releasing Hormone Analogs. Repeated administration of superactive analogs of gonadotropin-releasing hormone downregulate their receptors on gonadotroph cells, causing diminished secretion of LH and profound hypogonadism. This property has been employed in the treatment of metastatic prostate cancer since 1982.[48] The resulting chronic hypogonadism increases risk of fracture.[49,50]

Gonadal Steroids. Administration of all gonadal steroids—androgens, estrogens, and progestins—inhibits LH secretion and thereby lowers endogenous testosterone secretion. Although this suppression usually remits after discontinuation of the exogenous steroid, the effect may be prolonged if the dose is high and the duration long. The high doses of androgens that some athletes take to attempt to improve performance

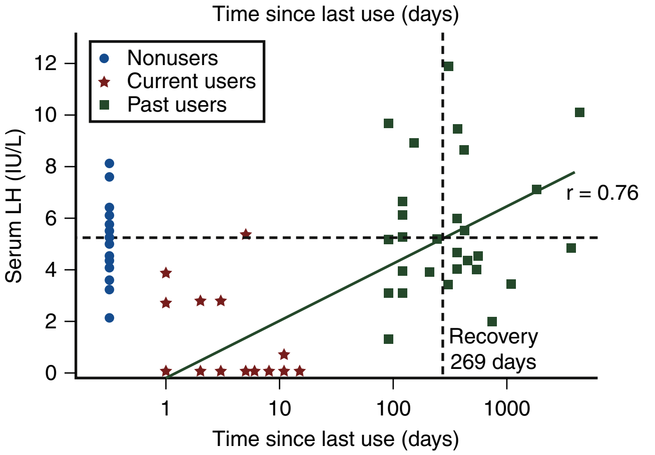

Fig. 107.9 Serum luteinizing hormone (*LH*) concentration as a function of time since discontinuing androgen abuse. (From Shankara-Narayana N, Yu C, Savkovic S, et al. Rate and extent of recovery from reproductive and cardiac dysfunction due to androgen abuse in men. *J Clin Endocrinol Metabol.* 2020;105:dgz324.)

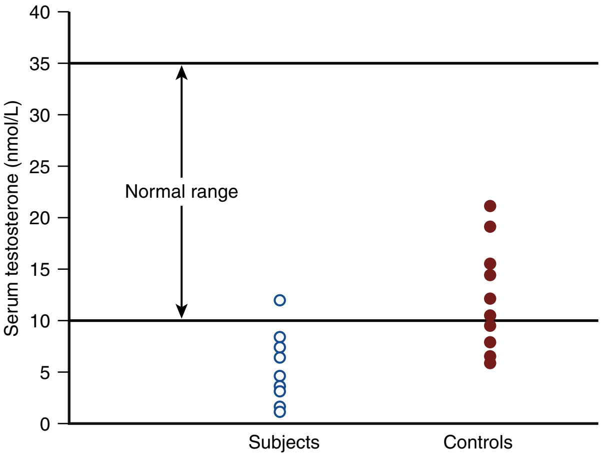

Fig. 107.10 Serum testosterone concentrations in ten men treated with intrathecal morphine for chronic pain and in ten men of similar age and with chronic pain not treated with an opioid. (From Finch PM, Roberts LJ, Price L, et al. Hypogonadism in patients treated with intrathecal morphine. *Clin J Pain.* 2000;16:251–254.)

may take months or even years to remit. In a metaanalysis of four studies involving 22 androgen users evaluated before, during, and after androgen administration, serum testosterone concentrations 13 to 24 weeks after discontinuation were an average of 271 ng/dL lower than before.[51] This phenomenon may be common in young men who seek testosterone treatment, as illustrated by the finding that, of 382 men being treated for hypogonadism at a urology clinic, 80 men, mean age 40 years, said they had previously taken androgenic steroids.[52] An observational study compared reproductive and cardiac parameters in 41 current and 31 former androgen users with those of 21 nonusers.[53] Current users had lower testis volume, sperm output, and serum inhibin B concentrations, as well as impaired cardiac systolic function, compared with nonusers. Variable times since previous use among former users, from 3 months to several years, allowed estimation of the time to recovery of the parameters. The mean time for recovery was 10.7 months for LH (Fig. 107.9), 19.6 months for FSH, and 14.1 months for sperm output. Cardiac function also improved. A longer duration of androgen abuse was associated with a longer duration of recovery.

Opioids. Administration of opioids, especially when chronically and in high doses, causes secondary hypogonadism, often to a marked degree. This effect was noted first in patients who were receiving the drugs intrathecally for chronic pain (Fig. 107.10),[54,55] but later was observed in patients who were taking preparations orally, especially sustained-acting preparations. In a metaanalysis of 15 studies involving 3250 patients, 63% were hypogonadal, more so if the drug was long-acting and if the dose was higher.[56]

Glucocorticoids. High-dose treatment with glucocorticoids can lower serum testosterone concentrations. One study reported that 16 men with chronic pulmonary disease who were treated with high-dose glucocorticoids for 1 month had a mean serum testosterone concentration of 211 ng/dL, compared with 449 ng/dL in 16 men matched for age and disease.[57]

Ketoconazole. Oral administration of ketoconazole, used to treat fungal infections or excessive cortisol secretion, inhibits steroid biosynthesis in both the adrenals and gonads by blocking cholesterol side chain cleavage, as well as blocking 17,20-desmolase, thereby blocking androgen production. Decreased testosterone production has been demonstrated *in vitro* and in response to acute administration in men, but sustained hypogonadism in response to chronic administration has not been demonstrated.

Cytotoxins. Alkylating agents can damage the seminiferous tubules and thereby decrease sperm production but have less of an effect on the Leydig cells and testosterone production.[58,59] The effects are greater when the drugs are given in childhood or adolescence and with longer duration of treatment. The effects may be reversible.

  Related to Estradiol/Testosterone Imbalance, 1814
  Related to Modulatory Hormones, 1815
  Other Causes, 1815
  Uncertain Causes, 1816
Treatment and Prevention, 1817

KEY POINTS

- Growth of male breast tissue (gynecomastia) is caused by high ratio of estrogen to androgen effect in the breast; this high ratio may be caused by low androgen or high estrogen serum concentrations, increased local aromatization of androgens to estrogens in the breast, or altered activation of the androgen or estrogen breast receptors.
- Other hormones, such as prolactin, growth hormone, insulin-like growth factor-1, and thyroid hormone, facilitate breast tissue growth when there is a relatively high ratio of breast tissue estrogen to androgen effect.
- Physiologic gynecomastia occurs commonly in neonatal boys, peripubertal boys, and older adult men.
- Most neonatal boys, peripubertal boys, and men with gynecomastia do not need an initial evaluation beyond a history and physical examination.
- Males with new onset of gynecomastia that is tender, >4 cm, or increasing size should be evaluated. The minimum evaluation is serum testosterone, follicle-stimulating hormone, and luteinizing hormone. Additional evaluation is based on the history, examination, and the results from the initial tests.
- Most males with gynecomastia do not need medical treatment. A 3-month trial of oral daily tamoxifen appears to be safe and effective in peripubertal boys and adult men with clinically significant gynecomastia.
- It is seldom necessary to recommend surgery as a treatment for gynecomastia. With rare exception (e.g., men whose ability to work might be affected by gynecomastia), surgery should only be recommended after treatment of the underlying cause of gynecomastia and only to males with significant, large, chronic gynecomastia (>5 cm).

PHYSIOLOGIC FORMS OF GYNECOMASTIA

Estrogens stimulate and androgens inhibit the growth and differentiation of mammary tissue.[1-3] Estradiol binds to estrogen receptors and stimulates ductal and glandular cells in the male breast. Testosterone exerts a generalized inhibitory action on growth and differentiation, perhaps through a specific antiestrogenic action.[2] The ratio between estrogens and androgens is the principal regulator of the development and maintenance of breast tissue in men. Prolactin, growth hormone, insulin, insulin-like growth factor 1 (IGF-1), and cortisol are permissive trophic factors that require an imbalance in estrogen and androgens to cause gynecomastia.[1] Several hormones alter the estrogen-to-androgen ratio and therefore may cause gynecomastia. Thyroxine increases the level of sex hormone–binding globulin (SHBG), a protein that binds testosterone more avidly than estradiol (thereby increasing the free estrogen-to-androgen ratio). Corticosteroids and prolactin lower circulating testosterone concentrations indirectly by suppressing hypothalamic secretion of gonadotropin-releasing hormone (GnRH).[4-6] Corticosteroids also directly inhibit testicular steroidogenesis.[7,8] The application of these physiologic principles provides a framework for evaluation of gynecomastia on a physiologic basis.

There are two phases of life when gynecomastia is due to normal physiology: just after birth and at the onset of puberty. In adulthood, nontender gynecomastia less than 4 cm is common, and there is often not an identifiable pathology. Nontender gynecomastia is particularly common in older men due to physiological changes that are associated with aging; some experts regard gynecomastia in older men as an effect of normal physiology.

Newborn Gynecomastia

The high concentrations of estradiol and progesterone produced by the mother during fetal life stimulate newborn breast tissue that persists for several weeks after birth in boys. Minimal galactorrhea called *witch's milk* occurs in up to 5% of newborn boys.[9] Galactorrhea is more common in infant boys with larger breast nodules at birth and may persist for 2 months or longer.

Pubertal Gynecomastia

In early puberty (average 11–12 years of age), approximately 30% of boys develop detectable gynecomastia (i.e., glandular tissue >0.5 cm in diameter). By 14 years of age, gynecomastia is detectable in approximately 65%.[10] While it is usually bilateral, gynecomastia is unilateral in 20% of pubertal boys. Spontaneous regression occurs in the majority of boys after 1 to 2 years; long-term gynecomastia persists in less than 5%.[10] There are variable hormonal alterations in pubertal boys with gynecomastia: low free testosterone, increased estradiol, elevated estradiol-to-testosterone ratio, and increased SHBG

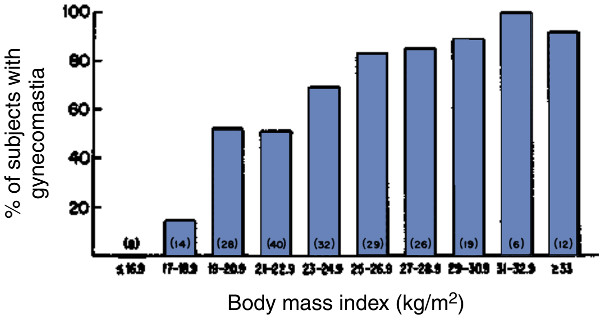

Figure 108.1 Correlation of percentage of subjects with gynecomastia and body mass index. (From Niewoehner CB, Nutall FQ. Gynecomastia in a hospitalized male population. *Am J Med.* 1984;77:633–638.)

concentrations.[11-16] The likely explanation for peripubertal gynecomastia is relative excess of circulating estrogen concentrations compared with circulating androgen concentrations due in part to highly variable aromatization of testosterone during early puberty.[15] In addition, recent data indicate that there are relatively higher concentrations of ERβ than ERα in stromal cells of breast tissue obtained from patients with pubertal gynecomastia. These data suggest that stromal ERβ receptors and associated downstream pathways play an important role in the development of pubertal gynecomastia.[17] In addition, polymorphisms of an estrogen receptor (leading to increased sensitivity to estrogen) may increase the risk of pubertal gynecomastia.[18]

Adult and Senescent Gynecomastia

The best definition of adult gynecomastia is benign glandular tissue that is palpable, greater than 2 cm in diameter, and generally extends outside the area under the nipple. A retrospective study of more than 500 adolescent boys and men who underwent chest computerized tomography for the evaluation of trauma demonstrated that the 90th, 95th, and 97.5th percentile of the diameter of normal breast tissue is 2.2, 2.6, and 3.6 cm, respectively.[19] The correlation of breast tissue volume or diameter between assessment by physical examination and radiographic imaging has not been systematically assessed, but radiographic tissue volume and diameter are highly correlated. Gynecomastia greater than 2 cm of palpable breast tissue is very common in normal ambulatory adults and in hospitalized patients. In a study of 306 normal military recruits (17–59 years of age), 36% had 2 to 4 cm of gynecomastia.[20] In this study, 4% had palpable breast tissue greater than 4 cm, but less than 1% had breast tissue greater than 5 cm. In another study of 954 young men (ages 18-26 years), the prevalence of gynecomastia (> 2 cm) was 40.5%.[21] Hospitalized patients have a higher prevalence of gynecomastia (up to 60%–70% in men over 45 years of age), and approximately 20% have gynecomastia greater than or equal to 5 cm.[22,23] The prevalence and diameter of gynecomastia increase with age and body mass index (Fig. 108.1).[21,23] Autopsy studies confirm the high prevalence of gynecomastia. In large autopsy series, the prevalence of breast tissue is approximately 40%.[24,25]

Most adult men with asymptomatic gynecomastia (i.e., found incidentally on physical examination) will not have an identifiable cause. Because asymptomatic gynecomastia less than 4 cm is so common in adult men, it is generally considered a normal variant or physiologic when there is no clearly identifiable cause. Note that there is no agreement that gynecomastia in adult men may represent a normal (physiologic) finding.[3,20,25]

The cause of physiologic adult gynecomastia in older men is not known, and it is likely to be multifactorial. Asymptomatic gynecomastia that is detected incidentally on physical examination is likely to have developed months or years earlier; the initial cause(s) might not be present. It is likely that age-related declines in serum free and total testosterone, age-related increases in obesity, environmental exposures, and systemic illness, contribute to the high prevalence of adult gynecomastia. In addition, older men often have used or been exposed to drugs and topical agents that decrease circulating or breast tissue androgen concentrations, block the effects of androgens, increase circulating and breast tissue estrogens, or have estrogen-like effects.

KEY POINTS

- Physiological gynecomastia occurs in the neonatal, pubertal, and late stages of adulthood. It is generally bilateral but may be asymmetric or even unilateral.
- Neonatal and pubertal boys commonly have small amounts (0.5–2 cm) of palpable breast tissue that may be tender. This breast tissue growth is due to changes in sex hormone concentrations that normally occur during these stages.
- In older adults, nontender breast tissue that is 2–4 cm in diameter and stable in size is considered physiologic gynecomastia. Nontender breast tissue <2 cm in adults is a normal variant.

PATHOLOGIC FORMS OF GYNECOMASTIA

There are two histologic subtypes of gynecomastia.[26,27] Histologic examination of breast tissue from men with recent onset of gynecomastia demonstrates glandular predominance: hyperplasia of the ductal epithelium, infiltration of periductal tissue with inflammatory cells, and increased subareolar fat. Histologic examination of breast tissue from men with asymptomatic, long-standing gynecomastia demonstrates stromal tissue predominance: dilated ducts with periductal fibrosis, stromal hyalinization, and increased subareolar fat.[28,29] The clinical correlate of these pathologic findings is that longstanding gynecomastia (with fibrosis) is unlikely to spontaneously remit even after resolution of the underlying cause of gynecomastia, but gynecomastia of recent onset may remit.

The clinical definition of pathologic and physiologic gynecomastia is *not* determined by histology. The important clinical distinction between pathologic and physiologic gynecomastia is to define the clinician's extent of evaluation and treatment. Many experts define pathologic gynecomastia pragmatically based on the epidemiology of gynecomastia. Because symptomatic (tenderness) and large (>4 cm in diameter) gynecomastia is uncommon in healthy young men, pathologic gynecomastia is defined as "tender, palpable breast tissue" or "nontender breast tissue >4 cm." Documented growth of breast tissue over time is also considered to be pathologic gynecomastia (even when the diameter is <4 cm). These definitions serve to limit extensive evaluation of gynecomastia, a common condition that is usually not indicative of significant underlying disease. Although these definitions of physiologic and pathologic gynecomastia are practical and clinically useful, they are empirical and not based on published longitudinal studies of men with gynecomastia.

Pathologic gynecomastia is caused by a deficiency of circulating and breast tissue androgen (usually testosterone) concentrations, inhibition of androgen effect on breast tissue, or an excess of circulating or breast tissue estrogen (usually estradiol) concentrations. Many causes of gynecomastia do not fit neatly into one category, but all are associated with an imbalance in the ratio of estrogen to androgen concentrations and/or their effects on the breast. However, it is clinically useful to determine whether the cause of the gynecomastia is due to a loss of the antiproliferative effects of androgen on the breast, an increase in the trophic effects of increased estrogen, or a disturbance of both.

TABLE 108.1 Common Causes of Gynecomastia in Adult (% Prevalence)

Persistent pubertal gynecomastia (25%)
Idiopathic with no detectable abnormality (25%)
Drugs 10%–25%
Hypogonadism 10%
Cirrhosis or malnutrition 8%–10%
Testicular tumors 3%
Hyperthyroidism 1%–2%
Chronic kidney injury 1%

There are many drugs, endocrinopathies, and systemic illnesses that may cause gynecomastia through these mechanisms. Of men with gynecomastia, the two most common etiologies are postpubertal (~25%) and idiopathic (~25%) gynecomastia.[30] Of the men who present with new onset of gynecomastia as adults, a majority (~60%) will have no detectable abnormalities. Drugs or medications and hypogonadism are the next most common causes (Table 108.1).

Related to Elevated Estrogen

Some causes of gynecomastia are driven more by estrogen excess than by androgen deficiency. Because circulating concentrations of estradiol (or other estrogens) inhibit pituitary gonadotropin secretion[31] and therefore reduce testicular production of testosterone, causes of gynecomastia due to estrogen excess are also associated with lower serum concentrations of testosterone.

Tumors. Testicular tumors of germ, sex cord, Leydig, or Sertoli cell origin can secrete an excess of estrogen or estrogen precursors.[32-42] When testicular tumors are the cause of gynecomastia, they are often large enough to be palpated patients,[41,42] but many, including Leydig cell tumors (the most common testicular hormone-secreting tumors), require detection by testicular ultrasound. Choriocarcinomas may produce human chorionic gonadotropin (hCG), a hormone that acts on luteinizing hormone (LH) receptors in the testes to stimulate production of estradiol and testosterone. Ectopic production of hCG by lung, kidney, liver, and gastric carcinomas also stimulates testosterone and estradiol production and causes gynecomastia; hCG and LH increase the activity of aromatase and therefore raise estrogen concentrations more than testosterone concentrations.[43,44]

Rarely, adrenal adenomas or carcinomas produce large amounts of estradiol.[45-47] Alternatively, the adrenal tumor secretes androstenedione, dehydroepiandrosterone (DHEA), and dehydroepiandrosterone sulfate (DHEAS), which are aromatized to estradiol. Patients with adrenal tumors as the cause of gynecomastia usually present with rapid onset of hypertension, elevated estradiol, DHEA, and DHEAS concentrations, and a large adrenal mass.[48]

Aromatase Excess. Overexpression of the aromatase is a unifying feature of several clinical causes of gynecomastia (Table 108.2). Overexpression of aromatase results in increased conversion of androstenedione to estrone and testosterone to estrogen. Obesity is associated with an increased total body production of aromatase, and in one study of 214 carefully assessed men, body mass index correlated significantly ($r = 0.52$) with breast tissue diameter.[49,50] Hyperthyroidism is also associated with increased total body aromatase.[51] Total body aromatase activity also increases with aging, perhaps because of the increased percentage of total body fat or age-related increases in circulating LH concentrations.[52,53]

TABLE 108.2 Aromatase-Associated Causes of Gynecomastia

Increased Amount of Aromatase Enzyme
Increased Activity in Normal Tissue
  1. Obesity
  2. Aging

    b. Hepatocellular carcinoma
    c. Melanoma
Hormonal Stimulation of Aromatase
Thyrotoxicosis
Idiopathic

Adapted from Braunstein GD. Aromatase and gynecomastia. *Endocr Relat Cancer*. 1999;6:315–324.

Familial gynecomastia, a rare cause of gynecomastia, is due to congenital overexpression of aromatase.[54] Early onset of gynecomastia is the most prominent initial clinical feature of these patients, but it is also associated with accelerated growth before puberty, decreased final adult height, and possibly reduced fertility.[54,55] Other familial disorders are associated with gynecomastia and testicular tumors. Peutz–Jeghers syndrome is associated with pigmented lesions around the mouth, colonic carcinoma, and Sertoli cell tumors.[56-60] These Sertoli cell testicular tumors may contain high amounts of aromatase. The Carney complex of pigmented, nodular adrenal hyperplasia, cardiac myxomas, and lentigenes is also associated with Sertoli cell tumors that often contain high amounts of aromatase.[60,61]

Several sporadic neoplasms cause gynecomastia through overexpression of aromatase. Isolated Sertoli cell tumors, choriocarcinomas, hepatocellular carcinomas, and adrenocortical adenomas, may overexpress aromatase that may cause gynecomastia.[34,38,45,62-64] Choriocarcinomas may cause gynecomastia by both overexpression of aromatase in the tumor and by neoplastic production of hCG that has LH-like effects on aromatase.[34,43,44,62]

There are hints in the literature that a mild increase in peripheral aromatase activity may be responsible for idiopathic gynecomastia in subsets of patients.[65] In one small study, 11 in 30 cases of idiopathic gynecomastia had aromatase excess evidenced by immunochemical assessment of biopsy tissue using a specific antiaromatase antibody.[66] Another study examined aromatase polymorphisms in DNA from whole blood in 100 men with gynecomastia compared with 99 healthy controls.[67] There was a marginally significant increase in T and TT single-nucleotide polymorphisms (SNPs) at *rs10046* in the 3′ untranslated region of exon 10 in the men with gynecomastia (40% vs. 26.3%, $P = 0.04$), but there was no direct evidence that these SNPs cause increased aromatase activity. In a case report, two patients with new onset of idiopathic gynecomastia had increased breast tissue aromatase mRNA compared with two patients with longstanding fibrotic gynecomastia.[68]

Excess Secretion of Estrogen Precursors. Congenital adrenal hyperplasia may cause gynecomastia through excess production of androstenedione, DHEA, and DHEAS, which are converted to estrone and then estradiol.[69-71]

Exogenous Estrogen and its Precursors

Estrogens. Several medications or topical creams provide estrogen or estrogenic substances for absorption and systemic action. Diethylstilbestrol (DES), which was used for treatment of prostate cancer, resulted in gynecomastia with a very high frequency, but it is no longer produced for human use, although it still can be obtained at pharmacies that compound medications.[72] Epidemics of gynecomastia have occurred in which an excess of estrogens present in meats was ingested. Regulatory agencies inspect for illegal feeding of DES or other estrogens to animals prior to slaughter.[73] The practice of estrogen use as an anabolic steroid for animals continues in some areas of the world and can cause gynecomastia in men who consume enough meat with residual contamination. Inadvertent ingestion of oral contraceptives by boys from their mothers' prescriptions or industrial exposure to oral contraceptives during the manufacturing process also can cause gynecomastia.[74] Other drugs such as digitoxin or digoxin have intrinsic estrogenic properties and stimulate breast enlargement.[75] Because this class of drug is administered to patients with severe systemic illnesses, other factors may also be involved in the development of gynecomastia.

Occupational and inadvertent secondary exposures may cause gynecomastia. Embalming fluid has estrogenic effects and may produce gynecomastia.[76] Unintended exposure to estrogen can occur from coital exposure to women using vaginal estrogen cream or even from women using estrogen-containing cosmetics.[77] Exposure of prepubertal boys to estradiol creams utilized as a skin cream by their mothers can cause gynecomastia.[78] In France, estrogen cream is distributed over large portions of the body as a means of transdermal estrogen delivery. Men may develop gynecomastia from secondary transfer with prolonged skin-to-skin contact with women who are applying these estrogen creams.

Estrogen Precursors. Exogenous androgens that can be converted to estrogen through aromatization are a common cause of gynecomastia. Intramuscular testosterone enanthate and cypionate increase estradiol concentrations substantially[79] and commonly result in gynecomastia for a few weeks after initiation of intramuscular therapy. This adverse effect is most common in hypogonadal boys during testosterone treatment, and it generally remits spontaneously (without treatment) after a few weeks to months after initiation of a physiologic dosage of intramuscular testosterone. Because transcutaneous formulations of testosterone are associated with smaller peaks in testosterone concentrations, physiologic dosages of these formulations may cause less gynecomastia. Adult athletes abusing anabolic androgenic steroids that are aromatizable and men being treated with high-dosage intramuscular testosterone for hypogonadism or contraception also may experience gynecomastia.[80,81] When hCG is given exogenously to men with secondary hypogonadism (due to hypothalamic or pituitary disease), it raises testosterone and estradiol concentrations, but because of its LH-like activity, hCG increases aromatization, resulting in a relatively high estrogen-to-androgen ratio, and therefore may cause gynecomastia. At physiologic dosages of hCG, the gynecomastia usually remits after several weeks to months.

Related to Testosterone Deficiency

Some causes of gynecomastia are driven more by androgen deficiency than by estrogen excess. However, most causes of androgen deficiency are associated with relatively greater absolute decreases in serum androgens compared to estrogens. Thus, even in states of androgen deficiency, there is a relative excess of estrogen.

Hypogonadotropic Hypogonadism. Patients with secondary hypogonadism due to hypothalamic or pituitary disease often have gynecomastia due to greater relative declines in serum testosterone than estradiol.[81] Cushing syndrome causes gynecomastia by at least two mechanisms. Glucocorticoids suppress hypothalamic secretion of GnRH and directly inhibit testosterone synthesis, resulting in lower circulating testosterone concentrations and a decreased testosterone-to-estrogen ratio.[4-6]

Anorchia. Fifty percent of anorchic patients also have gynecomastia, due to the absence of testicular androgens and adrenal secretion of aromatizable precursors of estrogen.[25]

Related to Estradiol/Testosterone Imbalance

Some causes of gynecomastia are driven equally by estrogen excess and androgen deficiency.

Hypergonadotropic Hypogonadism. Patients with primary hypogonadism tend to have more gynecomastia than men with secondary hypogonadism because of the dual effects of decreased circulating androgen and markedly increased circulating estrogen concentrations. The markedly increased circulating estrogen concentrations are due to the effects of LH to increase aromatization of testosterone. Klinefelter syndrome is the classic example of this hormonal profile.[81] Men with Klinefelter syndrome have reduced total serum testosterone, a greater reduction in free testosterone, and increases in circulating SHBG, estradiol, follicle-stimulating hormone (FSH), and LH concentrations, and approximately 85% of men with Klinefelter syndrome have gynecomastia. Men with Klinefelter syndrome often have gynecomastia before serum testosterone concentrations have declined below the lower limit of normal. All other forms of primary testicular disease, are associated with an increased risk for gynecomastia based on the same mechanism.[81,82]

Partially Compensated Testicular Dysfunction Associated with Aging. Androgen concentrations gradually decline with aging in men, with free testosterone concentrations declining to a greater extent than total testosterone concentrations.[83] As men age, circulating LH and FSH concentrations also tend to increase; as a result, estrogen concentrations decline to a lesser extent than androgen concentrations. These effects of aging increase the estrogen-to-androgen ratio, even when both circulating steroid concentrations remain in the normal range,[83] a finding that partially explains the high prevalence of gynecomastia in men older than 50 years of age.[22]

Androgen Resistance. A number of disorders and drugs cause decreased tissue responsiveness to androgen.[84-86] Because androgens inhibit breast development, these conditions are associated with gynecomastia. Male patients with complete androgen resistance have female-type breast development despite being genetically male (XY). Because the hypothalamus and pituitary gland of these genotypic males are also resistant to androgens, LH and testosterone are elevated in patients with androgen resistance, resulting in significantly increased circulating estradiol concentrations.

In syndromes of partial androgen resistance, a lesser degree of gynecomastia occurs due to the decreased antitrophic effects of androgen on the breast.[87-89] Kennedy syndrome is another form of androgen resistance due to the androgen receptor, a syndrome associated with variably expanded numbers of CAG repeats in exon 1 of the androgen receptor gene.[90] The diagnosis of Kennedy syndrome is usually delayed until the third to fifth decade.[90,91] Features of Kennedy syndrome include gynecomastia and neurodegenerative findings of symmetric muscular atrophy, weakness, and fasciculations of the bulbar, facial, and proximal muscles of the extremities.[90,91]

Systemic Illness. Any severe systemic illness may cause gynecomastia by causing transient or prolonged hypogonadotropic hypogonadism. Chronic liver disease and human immunodeficiency virus (HIV) infection may cause gynecomastia by additional mechanisms.

Chronic liver disease may produce gynecomastia through a number of mechanisms.[92] In addition to hypogonadotropic hypogonadism due to chronic liver disease, hepatopathy is associated with increased hepatic SHBG production and higher serum SHBG concentrations. As a result, serum free testosterone concentration declines disproportionately to the decline in serum total testosterone concentration. Acute alterations in nutritional state and ingestion of drugs such as spironolactone can further contribute. Of note, although liver disease is commonly believed to cause gynecomastia, one study found an equal prevalence of gynecomastia in hospitalized patients without and with liver disease.[47]

HIV infection may be associated with higher prevalence of gynecomastia, and multiple causes have been identified. The increased prevalence of gynecomastia in patients with HIV may be due to hypogonadism, increased use of illicit and prescription drugs known to cause gynecomastia, and severe chronic kidney or liver disease.[93,94]

Men with HIV infection are often treated with multiple antiretroviral drugs (highly active antiretroviral therapy [HAART]).[93-96] Any form of a HAART regimen may be associated with increased risk for prevalence of gynecomastia, but regimens that include efavirenz appear to be the most likely to cause gynecomastia.[93] The mechanism of HAART-induced gynecomastia is unknown, but one hypothesis is that HAART increases local production of interleukins that increase breast aromatase activity and/or directly stimulate breast growth.[93]

Related to Modulatory Hormones

Prolactin, growth hormone, IGF-1, and thyroxine modulate the actions of androgens and estrogens on breast tissue. Disorders of these hormones may cause or facilitate the development of gynecomastia.

Prolactin is a permissive lactotrophic hormone that stimulates breast growth when estrogen effects are relatively high compared with testosterone effects, but it is unlikely that prolactin directly causes gynecomastia, because many men with significant hyperprolactinemia lack this finding. Hyperprolactinemia, however, reduces GnRH (and therefore LH and testosterone) secretion in many men, lowering the ratio of circulating and tissue testosterone to estradiol concentrations. Therefore, prolactin commonly causes gynecomastia due to the combination of its permissive lactotrophic effects and suppression of circulating and tissue testosterone-to-estradiol concentrations. Prolactinomas and antidopaminergic drugs may cause gynecomastia; antidopaminergic drugs increase prolactin by blocking the tonic inhibitory effects of central dopaminergic pathways. A wide range of drugs with antidopaminergic actions is associated with increased prolactin concentrations.

Hyperthyroidism is commonly associated with breast tenderness and gynecomastia.[98-100] Thyroxine stimulates the production of SHBG, which binds circulating testosterone and estradiol: SHBG binds testosterone more avidly than estrogen.[101] Hyperthyroidism is also associated with increased aromatization of androgens to estrogens.[49] These effects of hyperthyroidism result in lower concentrations of unbound testosterone, higher concentrations of estradiol, and a lower ratio of circulating testosterone to estradiol.[102] Primary hypothyroidism is associated with hyperprolactinemia in women, but rarely in men.[103]

Growth hormone also has permissive trophic effects on breast tissue growth. Patients with acromegaly due to large pituitary tumors may have hypogonadotropic hypogonadism due to compression of the gonadotropes. In this setting of low androgen concentrations, growth hormone excess contributes to the development of gynecomastia. Because there are growth hormone receptors in breast tissue of men with gynecomastia, growth hormone induces breast tissue development directly.[104] It is also likely that growth hormone contributes to breast growth (at least partially) via increased circulating and tissue IGF-1 concentrations. In a recent small study, boys with significant peripubertal gynecomastia had higher serum IGF-1 concentrations than normal controls without significant peripubertal gynecomastia, and there were no significant differences in testosterone, estradiol, or in the ratio of testosterone-to-estradiol concentrations.[105] This study suggests that IGF-1 has a permissive and perhaps direct role in breast tissue development in boys. There have been a few case reports of gynecomastia attributed to exogenous growth hormone therapy in prepubertal boys.[106,107] Gynecomastia that occurs during growth hormone therapy usually spontaneously remits, but occasionally the growth hormone dosage must be decreased or discontinued.[107]

Other Causes

Drug-Induced. Drugs inhibiting testosterone biosynthesis, such as ketoconazole, may cause gynecomastia.[108] Several common drugs, such as cimetidine and spironolactone (but not eplerenone), inhibit the effects of androgens by binding to the androgen receptor.[84-86,] These drugs cause gynecomastia by two mechanisms: 1) reduction of the inhibitory effects of androgen on breast tissue and 2) interruption of negative feedback of testosterone on the pituitary gland, resulting in increased circulating LH concentrations, increased peripheral aromatization of testosterone to estradiol, and a lower testosterone-to-estradiol ratio. 5α-reductase inhibitors used to treat benign prostatic hyperplasia or androgenic alopecia cause gynecomastia in approximately 1% of men by reduced conversion of testosterone to the more potent androgen, dihydrotestosterone (and reduced overall androgen effect in breast tissue).[109] Cyproterone acetate, a drug available outside of the United States, has antiandrogenic effects and may cause gynecomastia.[110] Marijuana, a weak antiandrogen, has been associated with gynecomastia, although a small case-control series did not confirm this association.[111-113]

Treatment of prostate cancer with estrogens or with antiandrogens such as bicalutamide and flutamide frequently causes gynecomastia.[114,116] Approximately 50% of men with prostate cancer have gynecomastia, but multifactorial causes may be involved.[117] High-dosage cytotoxic chemotherapeutic drugs or irradiation can occasionally cause gynecomastia by producing transient or permanent decreases in testosterone production.[118-121] In one series of 190 men with metastatic testicular cancer treated with high-dosage cytotoxic chemotherapy, 4% developed gynecomastia 2 to 5 months after cessation of chemotherapy.[118] Gynecomastia may also occur after chemotherapy or bone marrow transplantation for lymphoma or other cancers.[122]

A large number of other drugs and environmental exposures have been reported to cause gynecomastia (Table 108.3).[84-86,106-160] For many of these drugs, it is not clear whether there is a causal relationship to gynecomastia.

Local Trauma. Trauma to the chest wall may cause gynecomastia, but causality remains unproven. In one small case series, 21 men developed gynecomastia (19 unilateral, two bilateral) after chest trauma.[142] Traumatic gynecomastia has been reported following thoracotomy, in military recruits wearing military packs, in patients with hip spica casts irritating the chest wall, following herpes zoster infection of the chest wall, and following local chest wall irradiation.[81,143] Spinal cord injuries also may rarely be associated with gynecomastia.[144,145]

TABLE 108.3 Drugs Associated with Gynecomastia

Exogenous Estrogens or Estrogenic Substances
Drug therapy with estrogens
Estrogen creams and lotions
Embalming fluid exposure
Delousing powder
Hair oil
Marijuana
Lavender and tea tree oils
Estrogen analogues: digitoxin
Nettle *(Urtica dioica)*
Exogenous Androgens or Luteinizing Hormone Analogs
Testosterone esters
Anabolic androgenic steroids
Human chorionic gonadotropin
Drugs That Inhibit Testosterone Synthesis
Opioids, corticosteroids, alcohol
Androgen-Antagonistic Drugs
Bicalutamide, cimetidine, flutamide, cyproterone, spironolactone
Blockers of 5α-Reductase Inhibitors
Finasteride, dutasteride
Uncertain Mechanisms
Drugs potentially associated with gynecomastia with uncertain mechanisms (incomplete list):
Angiotensin-converting enzyme inhibitors, amiodarone, amphetamines, atorvastatin (and other statins), auronofin, beta blockers, calcium channel blockers, cyclosporine, diazepam, etritinate, efavirenz (and other antiretrovirals), fenofibrate, fluoxetine, griseofulvin, heparin, isoniazid, metronidazole, omeprazole, phenytoin, pregabalin, quinidine, tacrolimus, and theophylline

Macrophages contain large amounts of aromatase, and it is possible that macrophage activity in areas of trauma could increase local breast estrogen production in trauma-induced gynecomastia.[146]

Uncertain Causes

Following World War II, starved prisoners developed gynecomastia upon refeeding. Starvation suppresses gonadotropin production, resulting in a biochemical pattern similar to hypogonadotropic hypogonadism.[147] The recovery phase with refeeding produces changes in testosterone and estrogen concentrations similar to early puberty. The resultant low testosterone-to-estrogen ratio is the likely cause of the gynecomastia that occurs with refeeding after starvation. "Refeeding gynecomastia" may occur in any man recovering from any chronic illness associated with undernutrition due to decreased caloric and nutrient intake or due to gut malabsorption. This mechanism is probably responsible for the gynecomastia observed in some patients with very poorly controlled diabetes mellitus, tuberculosis, and Hansen disease (leprosy).[148,149] Some men with a wasting syndrome from HIV infection may develop gynecomastia by a similar mechanism upon resolution of the wasting syndrome after an effective response to HAART.[150,151]

Pubertal Macromastia. *Pubertal macromastia* is the term used to describe unusually severe pubertal gynecomastia (i.e., female-appearing—Tanner stage III, IV, and V).[152] Unlike mild cases of physiologic pubertal gynecomastia, macromastia is much less likely to spontaneously remit. As with mild pubertal gynecomastia, there is generally no hormonal abnormality seen with macromastia. In one case series of 60 boys with macromastia, only seven had a primary endocrine abnormality or a systemic disease associated with increased aromatase activity.[153]

Idiopathic Gynecomastia. In the outpatient setting, the majority of patients with gynecomastia will have no detectable cause of the gynecomastia after careful endocrinological evaluation.[154]

Breast Enlargement Due to Malignancy or Infection. A carcinoma of the breast is very uncommon in men. Men with Klinefelter syndrome have an increased risk for breast cancer.[155] A firm, irregular, and unilateral mass is characteristic and suggests the diagnosis. Certain infectious diseases (e.g., Hansen disease, filariasis) may also cause breast enlargement due to infection of breast tissue.[156,157]

KEY POINTS

- Pathologic forms of gynecomastia are defined as gynecomastia >4 cm or of recent onset (<6 months) that may be tender (indicating active growth) or measurably growing over time. The causes of pathological gynecomastia are generally increased estrogen effects or decreased testosterone effects on the male breast tissue. There are a number of causes of gynecomastia with unknown mechanism, including refeeding gynecomastia, pubertal macromastia, and idiopathic gynecomastia. The most common cause of pathologic gynecomastia is idiopathic with no identifiable cause.

Evaluation. The first important step in the evaluation is to exclude pseudogynecomastia—fat tissue underneath the nipple. The appropriate technique for physical examination to detect gynecomastia is to pinch the tissue between thumb and forefinger lateral to the nipple or between fingers of both hands (Fig. 108.2). Breast tissue feels firm and rubbery with a firm edge. Ability to feel an edge of tissue at the interface of normal and glandular tissue confirms the presence of gynecomastia. Comparison of consistency with that of the fat tissue over the abdomen or along the axillary line of the breast is useful. Pressing down on the breast toward the chest wall is insensitive in detecting gynecomastia and is not useful. It is rarely necessary to use mammography to distinguish breast tissue from adipose tissue.[158-161] Ultrasonography can also be used when a patient refuses mammography or when mammography is infeasible, but it is generally a second-line imaging technique.[162-163]

A careful history and physical examination is generally sufficient to evaluate neonatal or peripubertal gynecomastia. It is also unnecessary to perform biochemical or radiographic evaluation in adult men with chronic, stable gynecomastia less than 5 cm in diameter. It is prudent to perform a more extensive evaluation in peripubertal boys with macromastia and adult men with new onset of gynecomastia, rapidly enlarging, eccentric, or hard, irregular masses, or gynecomastia greater than 4 cm in diameter. Firm, irregular lesions raise concern about neoplasm, and they should be evaluated by excisional biopsy.

History. The key questions are the following: (1) the time of onset, rate of progression, and degree of pain associated with the gynecomastia; (2) symptoms of androgen deficiency; (3) use of medications, prescription and nonprescription drugs, "nutritional" supplements, and skin products; (4) the presence of severe systemic disease such as poorly controlled diabetes mellitus or severe renal, hepatic, cardiac, or pulmonary disease that could suppress the hypothalamic-pituitary-gonadal axis or increase SHBG levels (e.g., hepatic disease); (5) recent nutritional deficiencies due to diet or gut malabsorption; (6) symptoms of underlying malignancy, especially testicular; (7) symptoms associated with estradiol, prolactin, growth hormone, cortisol, or thyroxine

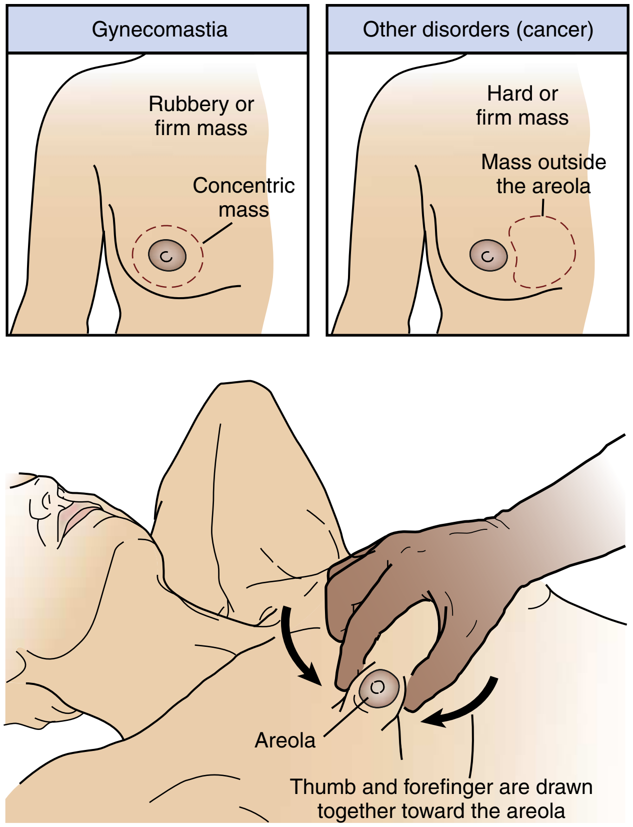

Figure 108.2 Method of examination to detect gynecomastia. **A,** Palpation by pressing down on tissue beneath the nipple in a supine patient is an insensitive method for detecting gynecomastia and is considered incorrect. **B,** Squeezing tissue between the thumb and forefinger in a sitting patient is a more sensitive technique and is considered correct. The examiner should try to palpate and "flip an edge" between the normal fat tissue and the glandular tissue to distinguish the outer limits of the gynecomastia. (Adapted from Santen RJ, Cerilli LA, Harvey JA, et al. In: Besser G, Thorner M, eds. *Comprehensive Clinical Endocrinology*. 3rd ed. Amsterdam: Mosby; 2002.)

excess; (8) a recent history of chest trauma; and (9) family history of gynecomastia.

It is important to specifically ask about the use of new skin products or medications by the patient or intimate contacts. There have been case reports of gynecomastia related to many skin products, including case reports of gynecomastia due to lavender oil and secondary exposure to estradiol cream used by a female partner or family member.[166,167]

Physical Examination. After using the "pinch test" to exclude pseudogynecomastia, the key elements of the physical examination are the following: 1) assessment for obesity with body mass index and examination for subcutaneous and abdominal adiposity; 2) assessment for evidence of malnutrition and severe systemic disease; 3) skin examination for signs of Cushing syndrome (striae, ecchymoses), acromegaly, and hyperthyroidism; 4) thyroid examination for goiter; 5) careful breast examination for galactorrhea or a hard, firm mass; 6) lymph node examination for large, hard, or fixed axillary lymphadenopathy; 7) deep palpation of the abdomen to detect large masses; 8) genital examination for hypospadias and assessment of testicular volume and testicular mass; and 9) assessment of evidence of other findings of systemic disease or endocrinopathy as indicated.

In peripubertal boys with macromastia and adult men with new onset of gynecomastia, rapid enlargement, and eccentric or hard, irregular masses or gynecomastia greater 4 cm in diameter, measurement of circulating testosterone, FSH, and LH concentrations is a reasonable initial laboratory assessment. Many experts recommend measurement of thyroid-stimulating hormone to detect subclinical hyperthyroidism. This recommendation is reasonable, and the test is relatively inexpensive, but, in the author's experience, it is not useful. Men with new onset of gynecomastia due to hyperthyroidism have clinical manifestations of hyperthyroidism, and gynecomastia is rarely (if ever) due to subclinical hyperthyroidism.

Many experts also recommend measurement of adrenal androgen and estrogen precursors such as DHEA or DHEAS, but these tests are not necessary in the routine initial evaluation. Adrenal sex-steroid–producing tumors are very rare causes of new onset gynecomastia, and are virtually always associated with large, bulky abdominal masses, abdominal pain, constitutional signs of malignancy, and suppressed gonadotropin levels. Measurement of estradiol and hCG concentrations is likewise not indicated on a routine basis. Tumors that produce estradiol or hCG will be associated with suppressed circulating FSH and LH concentrations.[168,169]

Finally, there is some debate about whether to measure estradiol concentrations on a routine basis. Commonly available commercial immunoassays for estradiol are notoriously inaccurate at the low concentrations typically found in men. Estradiol assays using tandem liquid chromatography followed by mass spectrometry are accurate in men, but these assays are more expensive and not widely available. The vast majority of men with gynecomastia have normal or only slightly elevated estradiol concentrations, and determination of estradiol concentrations does not affect the management of gynecomastia in these men. Because estradiol is a potent inhibitor of endogenous gonadotropin (and therefore endogenous testosterone) secretion, this author reserves measurement of estradiol and hCG for the rare patient with gynecomastia and suppressed circulating LH and FSH concentrations. When assessing for an hCG-producing tumor, it is best to use an assay with monoclonal antibodies that detects all forms of intact hCG and the free beta subunit of hCG.[172] Fig. 108.3 outlines a reasonable algorithmic evaluation of gynecomastia.

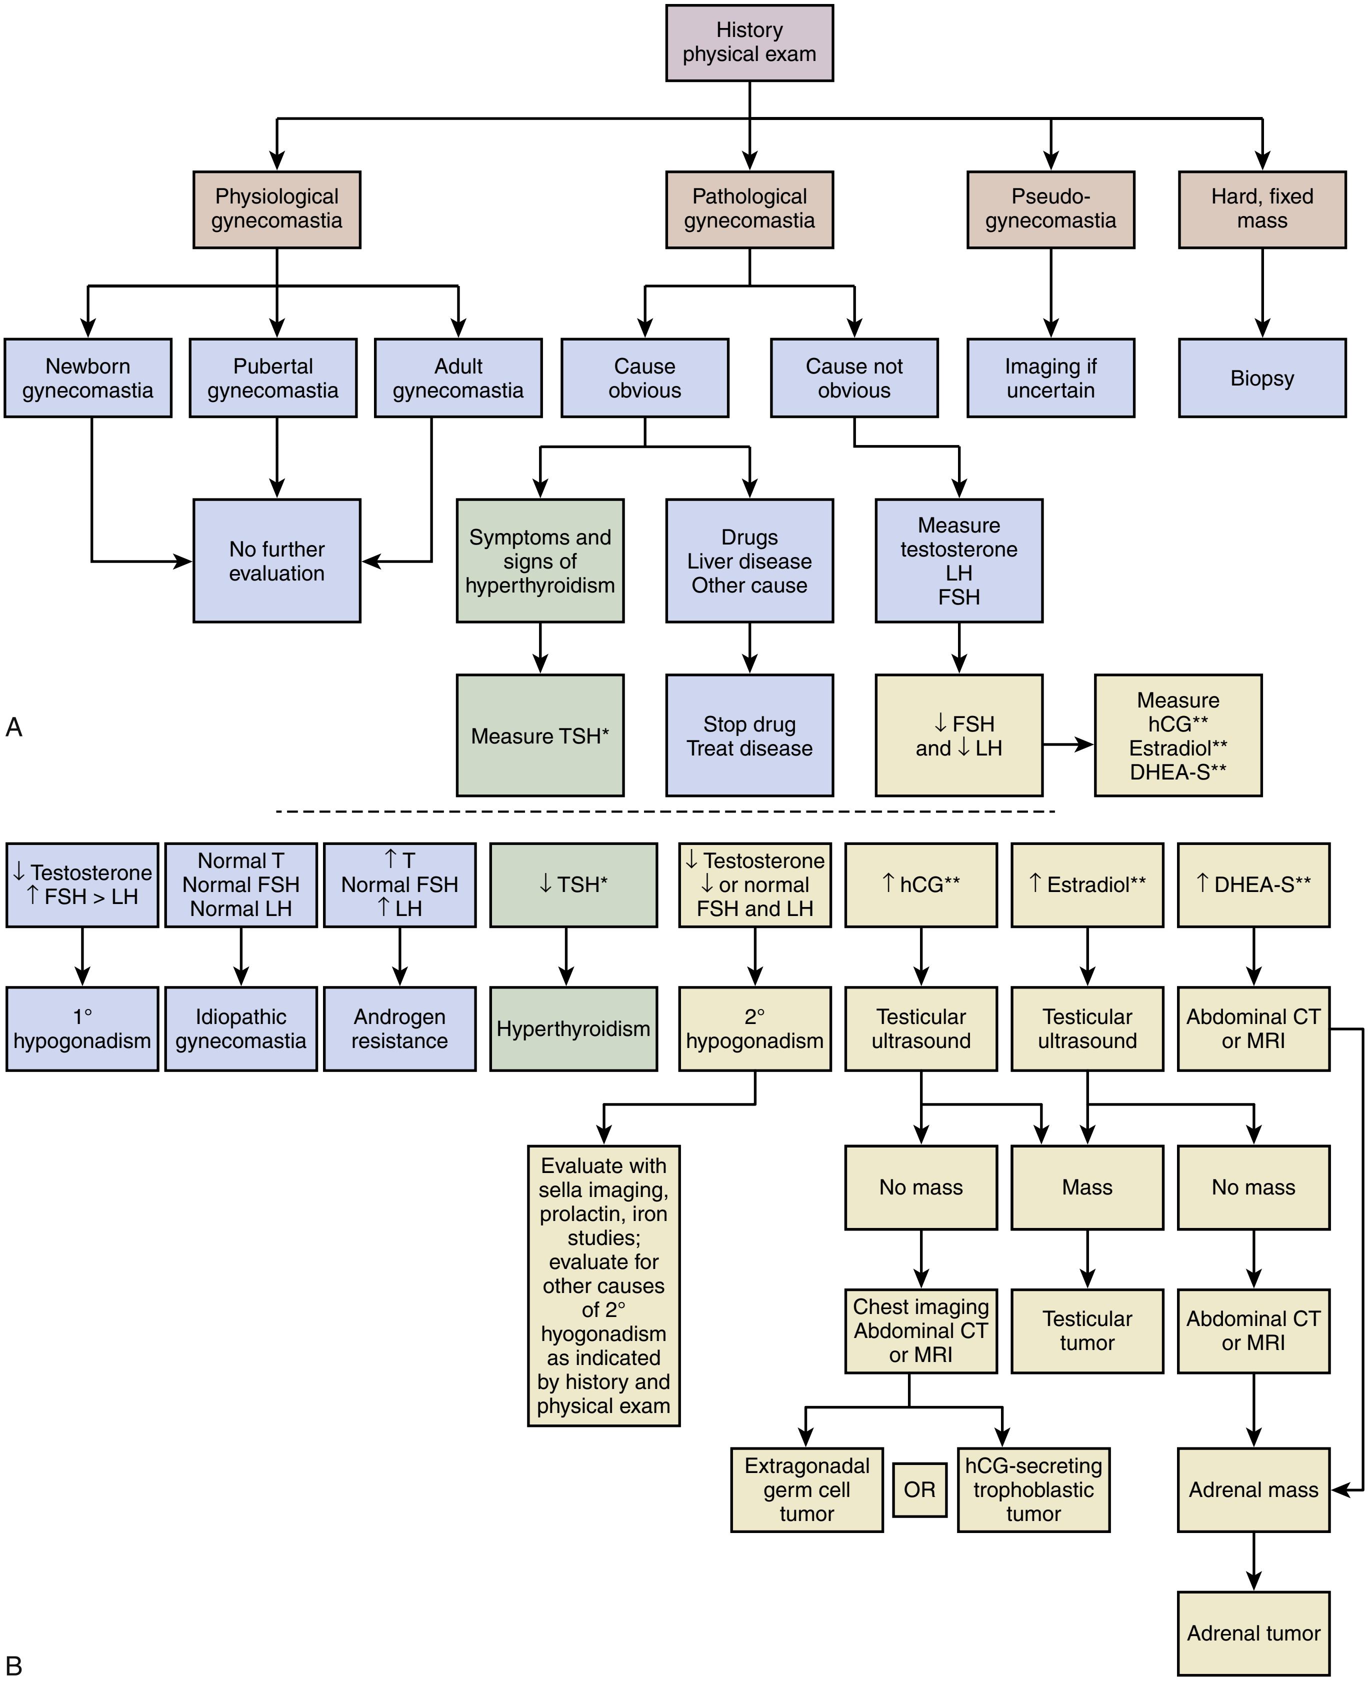
Imaging. As noted earlier, imaging is generally not required to make the diagnosis of gynecomastia. If a breast tumor is suspected, then imaging with mammography or ultrasound and obtaining tissue by fine-needle aspiration or core biopsy should be performed for pathologic examination.[158-165,170-175] In general, ultrasound does not add significant diagnostic information if a mammogram has been performed.[176]

KEY POINTS

- The diagnosis of pathologic gynecomastia is based on the history and examination.
- The evaluation for pathologic gynecomastia includes review of medications and topical agents associated with gynecomastia and history and physical examination for evidence of hypogonadism, hyperthyroidism, and chronic diseases, including kidney and liver disease. Measurement of serum testosterone, follicle-stimulating hormone, and luteinizing hormone in an early morning blood sample is generally the sole initial laboratory assessment. Further testing is based on the results of these tests and clinical suspicion of other systemic disease. Imaging is virtually never necessary unless breast malignancy is suspected based on palpation of a hard, immobile mass.

TREATMENT AND PREVENTION

Management of gynecomastia depends upon the clinical circumstances, severity, and presence of pain. The first principle is to stop



History physical exam
Physiological gynecomastia
Pathological gynecomastia
Pseudo-gynecomastia
Hard, fixed mass
Newborn gynecomastia

Figure 108.3 A, Algorithm depicting the initial evaluation of patients with gynecomastia. History and physical examination generally suffices to distinguish between the four most common categories of male breast enlargement *(pale blue boxes).* For men with recent onset of gynecomastia, increasing size, or breast diameter >4 cm, measurement of testosterone, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) is indicated. A serum thyroid-stimulating hormone (TSH) level should be performed if the patient has symptoms and signs of thyrotoxicosis *(yellow boxes).* Evaluation for causes of hypogonadotropic (secondary) and measurement of serum human chorionic gonadotropin (hCG), estradiol, and dehydroepiandrosterone sulfate (DHEAS) concentrations should be performed in men with pathologic gynecomastia and low serum testosterone and gonadotropin concentrations *(lavender boxes).* B, Interpretation and further evaluation after initial diagnostic evaluation of gynecomastia. *Some experts recommend measurement of serum TSH in all men with pathologic gynecomastia. **Some experts recommend measurement of serum hCG, estradiol, and DHEAS in all men with pathologic gynecomastia.

using offending drugs and treat any specific abnormality amenable to therapy. Boys with pubertal gynecomastia can be reassured that regression of breast tissue usually occurs after 1 year and at most after 3 years, and that no treatment is usually necessary.[10,11]

Studies of pubertal and adult gynecomastia require cautious interpretation, because gynecomastia resolves spontaneously, and most of the therapeutic trials do not use placebo controls for comparison. For example, in one randomized trial, investigators compared the aromatase inhibitor anastrozole with placebo in 80 boys with pubertal gynecomastia.[177] Although the aromatase inhibitor decreased estradiol concentrations in the active treatment arm, the percentage of patients with decreased breast tissue diameter was 38.5% with anastrozole and 31.4% with placebo (P = not significant). This study used state-of-the-art clinical trial methods and highlights the need for a placebo control in all clinical trials of medical therapy for gynecomastia.

Based on the pathophysiology of gynecomastia, responses to aromatase inhibitors would be expected both in pubertal and adult subjects. Although anecdotal reports suggested that aromatase inhibitors are effective, the clinical trials have yielded conflicting results.[177-181] The largest aromatase inhibitor study demonstrated no benefit for anastrozole over placebo in the treatment of significant pubertal gynecomastia (≥3 cm).[177] Because aromatase inhibitors cause adverse effects on bone (decreased bone density) and fat (increased total body fat), these drugs are not recommended for the treatment or prevention of gynecomastia.

Selective estrogen receptor modulators (tamoxifen, clomiphene, and raloxifene) have been shown to significantly reduce the amount of breast tissue in males with gynecomastia of recent onset.[182-195] Although these studies had methodologic flaws, it appears that this class of drugs can be used safely and effectively in the short term for some pubertal boys and adult men with recent onset of gynecomastia.

Treatment of Pubertal Gynecomastia. A prudent approach to management of pubertal gynecomastia is to observe for spontaneous regression and reserve medical therapy for boys with macromastia or significant persistent pain. Breast tenderness resolves within a few months in virtually all cases of pubertal gynecomastia, and breast tissue remits in approximately 80% of cases. Medical therapy for macromastia or very painful pubertal gynecomastia should wait until *after* any reversible cause of gynecomastia has been treated. Although there have been no trials with head-to-head comparisons, the data suggest that tamoxifen may be the most effective therapy. However, even for tamoxifen, the best-studied of the available medical therapies, the data are weak. A 2013 systematic review determined that only six of 164 publications on the use of tamoxifen in pubertal gynecomastia were worth including in the study; there were no randomized, controlled trials.[195] The authors concluded that tamoxifen appears to be safe and may be effective in the treatment of pubertal gynecomastia.

For macromastia or pubertal gynecomastia with significant pain and tenderness, it is reasonable to treat with tamoxifen (10 or 20 mg daily) for 3 months and reassess. For persistent (>2 years) pubertal macromastia, surgical excision may be considered. It is important to consult a surgeon who is experienced in mammoplasty to ensure optimal cosmetic results.

Treatment of Adult Gynecomastia. In adult men with gynecomastia, specific therapy for causative problems should be used when feasible, and offending drugs should be discontinued when possible. For example, eplerenone, a mineralocorticoid inhibitor without antiandrogenic effects, may ameliorate gynecomastia due to aldactone, a commonly used drug for cirrhosis and heart failure.[196,197]

In men with idiopathic gynecomastia, carefully controlled randomized studies of medical therapy are limited. Two studies compared tamoxifen with placebo and detected a reduction in size in 10 of 16 (62%) men receiving the drug and one of 16 men receiving placebo. Pain relief occurred in nine of 10 on tamoxifen and one of 10 with placebo.[182,183] Three noncontrolled trials reported six of 16 (37%) with size reduction and 13 of 15 (87%) with pain relief.[184-186] Danazol, a weak androgen, and dihydrotestosterone, a nonaromatizable androgen, have also been shown in small trials to be modestly effective in the treatment of gynecomastia, but neither androgen is used commonly in the treatment of gynecomastia.[198]

Based upon these data, a trial of tamoxifen 20 mg daily for 3 months may be useful in some patients with recent-onset, very symptomatic, idiopathic gynecomastia. If gynecomastia persists for more than 1 year and is cosmetically very bothersome, reduction mammoplasty may be necessary. A surgeon who has experience with this procedure should be selected in order to achieve optimal cosmetic effects with a minimally invasive procedure.[199-202]

Prevention of Adult Gynecomastia. Prevention of gynecomastia may be useful in men undergoing antiandrogen therapy for treatment of prostate cancer. Prophylactic tamoxifen is the best-studied effective preventive therapy. Prophylactic tamoxifen reduces the frequency of gynecomastia due to antiandrogen therapy for prostate cancer by 60% to 80%.[203-207] Prophylaxis with low-dosage irradiation of the breast also reduces the incidence of gynecomastia in men treated with antiandrogen therapy, but this preventive treatment is rarely used now, in part because tamoxifen appears to be more effective.[208-216]

KEY POINTS

- Gynecomastia is generally treated by managing the underlying cause. Medical therapy is seldom indicated. For patients with severe persistent breast tenderness due to pubertal idiopathic gynecomastia, a short course of tamoxifen (<6 months) may be beneficial. Breast reduction surgery is reserved for those men who are very bothered by the amount of breast tissue, and this surgery should be delayed until the underlying cause has been treated and breast tissue growth and tenderness has resolved for at least 6 months.

Conclusions, 1842

INTRODUCTION

Erectile dysfunction (ED) is a pervasive disorder defined as the persistent inability to achieve and/or sustain penile erection adequate for sexual satisfaction.[1] This definition from the International Consultation on Sexual Medicine incorporates not only the mechanics of obtaining and maintaining an erection but also critical subjective factors, including overall sexual satisfaction, bother, and interpersonal dimensions, which are critical determinants of clinically relevant ED. Although dysfunction of penile erection is the most widely recognized male sexual condition, other conditions, such as decreased libido, premature ejaculation (PE), delayed ejaculation (DE), and Peyronie disease (PD), may sometimes be comorbid with or confused for ED.

In this chapter, we will focus on the evaluation and management of the man presenting with difficulty attaining or maintaining penile erection. We will review penile anatomy, mechanisms of penile erection, and the pathogenesis of ED, in addition to reviewing diagnostic modalities and medical and surgical therapeutic options for the treatment of ED. Next, we will briefly review related male sexual health issues, including disorders of ejaculation and orgasm, PD, and priapism, which may be associated with ED but are less commonly addressed due to persistent social stigma. Finally, we will review future directions in the development of therapeutics for ED.

We hope to provide a reference for all clinicians regarding optimal management of ED and to improve the reader's understanding of the physiological basis of penile erection and how vascular, neuronal, hormonal, iatrogenic, and psychosocial factors operate in concert together to produce or inhibit penile erection.

GUIDELINES

When treating patients with ED, it is valuable to recognize that many professional medical societies have published recent guidelines regarding best practices related to the condition. Written by well-respected experts in the field of sexual medicine, these are living documents that continually evolve as medical knowledge expands and technology advances. The European Association of Urology has published a thorough set of male sexual health guidelines including disorders such as ED, ejaculatory disorders, decreased libido, and penile curvature.[2] The American Urological Association (AUA) has published the recent guidelines on ED, which is a current, evidenced-based document that describes algorithms for both the medical and surgical management of ED.[3] The AUA has also recently updated its guidelines on testosterone (T) therapy, another evidence-based document that provides direction on the related topic of androgen insufficiency.[4] The Endocrine Society also has recently published guidelines on the evaluation of hypogonadism and treatment with T therapy.[5] PE is another common male sexual concern,[6] and recent guidance from the International Society of Sexual Medicine provides an algorithm for management of this poorly understood yet disturbing condition.[6,7] Becoming acquainted with these and other evidence-based guidelines documents, which are available online to all clinicians, will not only facilitate patient encounters but also improve quality of care and reduce risk for male sexual dysfunction patients.

EPIDEMIOLOGY

In the Massachusetts Male Aging Study, a community-based survey of men between 40 and 70 years of age, 52% of respondents reported some degree of ED: 17% mild, 25% moderate, and 10% complete.[8] Although the prevalence of mild ED remained constant (17%) between the age of 40 and 70 years, there was a doubling in the number of men reporting moderate ED (from 17% to 34%) and a tripling in the number of men reporting complete ED (from 5% to 15%).[9] More than 70% of men over 65 years reported that they are sexually active. However, 40% were dissatisfied with their sexual function.

Among the major predictors of ED are hypertension, hyperlipidemia, diabetes mellitus, and heart disease. Risk of ED increases with smoking and appears to do so in a dose-dependent manner.[10] There is also a higher prevalence of ED in men who have undergone radiation or surgery for prostate cancer or other pelvic conditions such as malignancy or large bowel disease. The psychological correlates of ED include decreased self-esteem, depression, anxiety, anger, and relationship dissatisfaction.[11] Other male sexual dysfunctions, such as PE, DE, and decreased libido, have also been found to be highly prevalent and comorbid in men with ED.

Classification of Erectile Dysfunction Based on Pathogenesis

Penile erection is a multidimensional process that involves the complex interplay among psychological, organic, and relational components. When any of these components is altered, ED may result. Often, clinicians attempt to over simplify the condition by seeking to classify its etiologies into organic and psychogenic groups (Table 109.1). This unquestionably helps to identify a good starting point for treatment. Most commonly, however, "organic" ED involves a significant psychological component, as ED universally inflicts a negative effect on mood, interpersonal relations, and quality of life. In the 1950s, 90% of cases of ED were believed to be exclusively psychogenic in origin. Currently, most clinicians believe that mixed ED is most commonly encountered. The classification system of ED most frequently utilized for research encompasses organic, psychogenic, and mixed etiologies of ED and is endorsed by the International Society of Impotence Research (Table 109.2). This classification provides an excellent framework for beginning the clinical evaluation of a male with complaints of sexual dysfunction.

Psychogenic Erectile Dysfunction

Many psychological conditions can either trigger or aggravate ED. Sexual behavior and penile erections are controlled by the hypothalamus, cerebral cortex, and limbic systems. Given the number and complexity of known and as-yet-unidentified factors involved, it is not surprising that the pathogenesis of psychogenic ED is still under investigation. Possible mechanisms proposed include an imbalance of central neurotransmitters, overinhibition of spinal erection center by the brain, inadequate nitric oxide (NO) release, and sympathetic overactivity.[12]

TABLE 109.1 **Information Gained from Patient History that Helps to Distinguish Psychogenic from Organic Erectile Dysfunction, Which May Be Helpful in Determining the Most Useful Therapeutic Options for the Patient**

Psychogenic	• Sudden onset • Intermittent • Situational (erection may be intact in certain situations, such as with self-stimulation, but not in others, such as with a partner or specific partner) • Loss of ability to maintain erection • Nocturnal erections intact • Likely to respond well to PDE5 inhibitors if libido is intact
Organic	• Gradual onset • Progressive • Consistently poor erections despite situation • Difficulty with obtaining and maintaining erection

Organic Erectile Dysfunction

Sexual function gradually declines as men age, though this decline should not be considered any more acceptable than the development of diabetes, hypercholesterolemia, or hypertension, which also increase in incidence with age. It is physiologically normal for the aging male to anticipate the latency period between sexual stimulation and erection to increase, the refractory period between erections to increase, the erection to be less rigid, ejaculation to be less forceful, and ejaculate volume to decline.[8] Aging is also associated with a decrease in penile sensitivity to tactile stimulation, a gradual decrease in serum T concentration, and an increase in cavernous muscle tone.

ED is more common in patients with neurologic disorders, such as Parkinson or Alzheimer diseases, stroke, or traumatic brain injury, and it is estimated that up to 20% of all ED is neurogenic in origin. This may be due to both a decrease in libido and/or inability to initiate the erectile process. Spinal cord injury patients have varying degrees of ED chiefly determined by the location and extent of the spinal cord lesion. Men with sacral spine lesions may have disruption of the sacral reflex arc and may not respond to genital stimulation. Men with thoracic spinal lesions may retain reflexogenic erections but lose psychogenic erections, which are generated by suppression of sympathetic penile tone in response to erotic stimuli. Although erections of some form are often possible in men with spinal cord injury, they are typically less rigid and of shorter duration compared with those in men without spinal cord injury. Even in men without spinal cord injury, sensory input from the genitalia remains essential to achieving and maintaining reflexogenic erection. This input may be compromised due to peripheral neuropathy in men with diabetes and other chronic medical conditions such as renal insufficiency.[13]

Multiple chronic medical conditions contribute to the development and progression of ED. Chronic diabetes mellitus is highly associated with ED, in that it causes neurogenic, hormonal, and vascular consequences. In addition to its effect on small vessels, it may also affect the cavernous nerve terminals and endothelial cells, resulting in deficiency of neurotransmitters. Additionally, corporal smooth muscle relaxation in response to NO may also be impaired, possibly due to the accumulation of glycosylation products. Many diabetic males also have low serum T as a consequence of the disease. Chronic renal insufficiency is commonly associated with ED, impaired libido, and infertility. The mechanism is likely multifactorial and includes low T and decreased libido, vascular insufficiency, polypharmacy, and neuropathy.

TABLE 109.2 **The Erectile Dysfunction Classification System Recommended by the International Society of Impotence Research that was Created Due to the Need for Standardization of Definitions and Terms Used in the Diagnosis and Treatment of the Disorder and Later Modified to Include Specific Conditions That May be Associated with Each Classification**

Psychogenic

1. Generalized type
    - A. Generalized unresponsiveness
        - a. Primary lack of sexual arousability
        - b. Aging-related decline in sexual arousability
    - B. Generalized inhibition—chronic disorder of sexual intimacy
2. Situational type
    - A. Partner-related
        - a. Lack of arousability in specific relationship
        - b. Lack of arousability due to sexual object preference
        - c. High central inhibition due to partner conflict or threat
    - B. Performance-related
        - a. Associated with other sexual dysfunction/s (e.g., rapid ejaculation)
        - b. Situational performance anxiety (e.g., fear of failure)
    - C. Psychological distress or adjustment-related
        - a. Associated with negative mood state (anxiety, depression) or major life stress (death of partner, divorce, loss of employment, illness)

Organic

1. Neurogenic
    - Central nervous system: spinal cord injury, multiple sclerosis, cerebrovascular accident
    - Peripheral nervous system: neuropathy
    - Iatrogenic from surgery or radiation
2. Hormonal
    - Hypogonadism
    - Hyperprolactinemia
    - Diabetes mellitus
    - Thyroid disorders
3. Arterial
    - Hypertension
    - Dyslipidemia
    - Obesity and sedentary lifestyle
    - Renal insufficiency
    - Tobacco smoking
    - Chronic obstructive pulmonary disease
    - Sleep apnea
    - Coronary artery or peripheral arterial disease
    - Focal arterial occlusion after trauma
4. Cavernosal
    - Venoocclusive disease
    - Age-related muscle atrophy
    - Cavernosal fibrosis of the penis
    - Peyronie disease
    - Penile fracture
5. Drug-induced
    - Antihypertensives
    - Antidepressants
    - Antiandrogens
    - Marijuana
    - Opiates

Mixed Organic/Psychogenic = most frequently encountered type of erectile dysfunction

Endocrinologic conditions may also contribute to ED. Androgen deficiency and androgen deprivation therapy for prostate cancer are associated with decreased libido and less frequent nocturnal erections. However, erectile response is preserved in many men with low serum T, suggesting that androgens are beneficial but not essential for erection. Hyperprolactinemia has been linked to sexual dysfunction, as prolactin has an inhibitory effect on both central dopaminergic activity and gonadotropin-releasing hormone secretion.

Vascular disease is a common and important cause of ED. Common vascular risk factors associated with generalized penile arterial insufficiency include hypertension, hyperlipidemia, cigarette smoking, and diabetes mellitus. Focal stenosis of the common penile artery is uncommon but can be a cause of ED in men who have sustained repetitive or severe pelvic or perineal trauma, such as with biking accidents or pelvic fractures. Venoocclusive dysfunction results from disruption of the blood-trapping capacity of the tunica albuginea: insufficient compression of the subtunical venules allows for rapid drainage of blood soon after filling, leading to loss of erection. Venous-leak ED may also be the result of degenerative conditions that affect the penis, including PD, penile scarring, trauma, and diabetes mellitus. Commonly found in young men, venous leak can also be seen in anxious men with excessive adrenergic tone causing structural alterations of the cavernous smooth muscle and endothelium in addition to insufficient trabecular smooth muscle relaxation.[14]

Many drugs are associated with ED, with some classes more commonly associated with sexual side effects than others (Table 109.3). Antipsychotics and antidepressants may disrupt central neurotransmitter pathways involved in sexual function. Antihypertensives are hypothesized to contribute to ED by decreasing the availability of blood to the corporal arteries. However, angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are less likely to cause ED than beta-adrenergic blocking drugs, which potentiate a-1 adrenergic activity. Thiazide diuretics cause ED via an unknown mechanism.

Cigarette smoking acutely induces vasoconstriction and penile venous leakage secondary to the contractile effect on the cavernous smooth muscle, and chronic use likely accelerates atherosclerotic changes in the penile microvasculature over time. Alcohol in small amounts may improve erections and increase libido because of its vasodilatory effect and the suppression of performance anxiety, but increased use may cause sedation, decreased libido, and transient ED. Chronic alcoholism can cause hypogonadism and polyneuropathy, among other harmful conditions.

KEY POINTS

- Erectile dysfunction (ED) is defined as the persistent inability to achieve and/or sustain penile erection adequate for sexual satisfaction. Penile erection is a complex process that involves the interplay among psychological, organic, and relational components. When diagnosing the etiologies of ED, it is helpful to consider both organic and psychogenic causes with the understanding that the majority of patients have "mixed" ED with multiple etiologies. Common factors contributing to ED are drugs (prescription and nonprescription); tobacco and alcohol misuse; psychological, neurological, endocrinologic, and vascular disease states; and age-related changes.

TABLE 109.3 Medical Conditions and Medications Frequently Associated with Erectile Dysfunction

Condition	Medication Associated with Erectile Dysfunction
Antihypertensives	Thiazide diuretics Beta-blockers Spironolactone
Atrial fibrillation	Digoxin
Benign prostatic hyperplasia	Alpha-blockers 5 alpha reductase inhibitors
Chronic pain	Opiates
Gastroesophogeal reflux disease	H2-blockers
Prostate cancer	Antiandrogens Luteinizing hormone–releasing hormone agonists Luteinizing hormone–releasing hormone antagonists
Psychiatric conditions	Antipsychotics Benzodiazepines Phenytoin Selective serotonin reuptake inhibitors Tricyclic antidepressants

PENILE PHYSIOLOGY

Anatomy of the Penis

The penis is a highly dynamic organ with complex anatomy that facilitates its functions for sexual reproduction. The penis is grossly made up of three anatomic structures: the paired corpora cavernosa, and the corpus spongiosum, which surrounds the urethra and terminates at the glans penis. These structures are contained in the penile shaft by the tunica albuginea, which is composed of a dense network of elastin fibers on which collagen fibers rest (Fig. 109.1). The tunica of the corpora cavernosa is a bilayered structure.[15] The inner circular layer supports and contains the cavernous tissue and projects intracavernosal pillars that connect to the midline septum of the tunica. These pillars, or struts, and the midline septum provide structural support to the corpus cavernosum during erection. The outer layer of the tunica is oriented longitudinally and extends from the crura of the penis proximally to the glans penis distally. These fibers insert into the inferior pubic ramus and are absent ventrally between the 5- and 7-o'clock positions. The corpus spongiosum, which surrounds the urethra and ends in the bulbous glans penis, lacks an outer layer and has no intracorporal pillars. This ensures a low-pressure, compliant structure during erection/intercourse and expulsion of the ejaculate fluid. Emissary veins pierce the outer bundles obliquely and run between the inner and outer layers of the tunica of the corpora cavernosa for a short distance. Branches of the dorsal artery take a more direct perpendicular route through the tunica and are surrounded by a fibrous sheath.[16]

The arterial blood supply to the penis comes from the paired internal pudendal arteries. The pudendal divides into the dorsal artery (to skin, subcutaneous tissue, glans penis), the bulbourethral artery (to the corpus spongiosum), and the cavernous arteries (to the corpora cavernosa). Accessory pudendal arteries may also supply a major portion of the penis, and these arteries tend to originate from the external iliac or obturator arteries. Collaterals among the three branches are frequently encountered. The venous drainage of the penis is also multiple. The venous drainage of all three corporal bodies originates in the corporal subtunical venules, which unite to form the emissary veins. The mid and distal corpora cavernosa drain via the deep dorsal and periarterial veins to the preprostatic plexus, while the proximal portion drains via the cavernous and crural veins to the preprostatic plexus and internal pudendal vein. The glans penis drains via the deep dorsal and dorsal veins, and the corpus spongiosum drains via the circumflex, urethral, and bulbar veins. The penile skin and subcutaneous tissue drain via the superficial dorsal veins, which then empty into the saphenous veins.

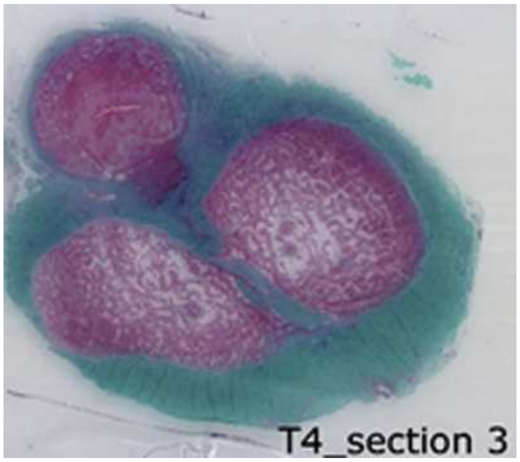

Figure 109.1 **Trichrome histology slide showing a cross section of the penis.** The paired corpora cavernosa and the singular corpus spongiosum are stained pink, and the tunica is stained blue. (Image courtesy of Lia Banie.)

Hemodynamics of Penile Erection

The penile erectile tissue, composed of cavernous, arteriolar, and arterial wall smooth muscle, is fundamental to the erection process. The erection process can be divided into six phases (Table 109.4). In the flaccid state, the vascular smooth muscles are tonically contracted secondary to baseline adrenergic discharge. This allows only a trickle of arterial flow, which is all that is needed to adequate to maintain cellular respiration. The blood partial pressure of oxygen (PO_2) in the flaccid state is approximately 35 mm Hg.

Activation of the cavernous autonomic nerves produces a full erection secondary to rapid filling and trapping of blood in the paired corpora cavernosa.[17] When the penile smooth muscle relaxes secondary to neurotransmitter release, resistance to incoming arterial flow drops to a minimum. This leads to arterial and arteriolar vasodilatation and expansion of the sinusoids to receive a large volume of arterial blood. The rapid delivery and trapping of blood in the penile sinusoids cause the corpora cavernosa to lengthen and widen until the capacity of the tunica albuginea is reached. The sinusoidal walls expand and push outward against the tunica albuginea, resulting in compression of the subtunical venous plexus. Stretching of the layers of the tunica albuginea compresses the emissary veins and effectively reduces the venous flow to a minimum.[17] Intracavernous pressure (ICP) and PO_2 increase to approximately 100 and 90 mm Hg, respectively, raising the penis from a dependent position to the erect state. Contraction of the ischiocavernosus muscles (somatic nerves) causes ICP to increase further, to several hundred millimeters of mercury and well above systolic blood pressure, resulting in rigid erection.[18,19]

During erection, the hemodynamics of the corpus spongiosum and penile glans are distinctly different from those of the corpora cavernosa because of the lack of the outer layer of the tunica albuginea. Arterial flow increases in a manner similar to that in the corpora cavernosa, but the glans functions as an arteriovenous fistula during the full erection

TABLE 109.4 The Six Phases of Penile Erection

Phases of Penile Erection

1. **Flaccid**
    - Minimal arterial or venous blood flow, with blood gas values equal to venous blood.
2. **Filling (Latent)**
    - Increased flow in the cavernous artery during systole and diastole.
    - Unchanged intracavernous pressure.
3. **Tumescence**
    - Climbing intracavernous pressure until full erection is achieved.
    - Expansion and elongation of the penis with visible pulsation.
    - Arterial flow decreases as the pressure rises.
    - Intracavernous pressure rises above diastolic pressure so flow occurs only during systole.
4. **Full Erection**
    - Intracavernous pressure can rise to as much as 80%–90% of the systolic pressure, with blood gas values similar to arterial blood.
5. **Rigid Erection**
    - Contraction of the ischiocavernous leads to intracavernous pressure well above systolic pressure, leading to complete rigidity.
    - Almost no blood flow through the cavernous artery for the short duration of rigid erection.
6. **Detumescence**
    - After ejaculation, tonic sympathetic discharge resumes.
    - Smooth muscle contracts around the sinusoids and arterioles.
    - Arterial flow returns to flaccid levels, and venous channels reopen.
    - The penis returns to its flaccid length and girth.

Adapted from Smith & Tanagho's General Urology, 19th Ed.[5]

phase. Perhaps this is to serve as a cushion for the corpora during intercourse or to serve as a conduit for the ejaculate after orgasm. Nevertheless, during rigid erection, most of the venous channels are temporarily compressed, and further engorgement of the glans can be observed.[17]

Innervation of the Penis

Humans are known to have three types of erections based on the source of the erection. *Genital-stimulated erections* are contact, or reflexogenic, erections that are provoked by physical contact with or stimulation of the genitals. This type of erection is preserved in patients with upper spinal cord lesions, though erection is usually limited in duration and poorly controlled by the patient. *Central-stimulated erections* are more complex and are noncontact, or psychogenic, erections provoked by memory, fantasy, or audiovisual stimuli. *Central-originated* erections are erections that occur during sleep or spontaneously without any type of intentional stimulation.[15] Most sleep-related erections occur during rapid eye movement sleep, with the activation of cholinergic neurons in the lateral pontine tegmentum but suppression of adrenergic neurons in the locus coeruleus and serotonergic neurons in the midbrain raphe.[15,20] Of note, central-originated, or sleep-related, erections are significantly reduced in men with hypogonadism.[20]

Penile erection is a complex neurologic process that involves the interplay amongst the sympathetic, parasympathetic, and somatic nervous systems. The autonomic spinal erection center is located in the intermediolateral nuclei of the spinal cord at levels S2 to S4 and T12 to L2. Nerve fibers from the thoracolumbar (sympathetic) and sacral (parasympathetic) spinal segments unite to become the inferior hypogastric and pelvic plexuses, which send branches to the pelvic organs. The cavernous nerves are the fibers that innervate the penis; these nerves course posterolaterally along the seminal vesicles to the prostate and continue through the genitourinary diaphragm along the membranous urethra. Some of these fibers travel with the cavernous and bulbourethral arteries to enter the corpora cavernosa and corpus spongiosum. Others travel distally with the dorsal nerve of the penis to enter the corporal bodies in various locations to supply the mid and distal portions of the penis and urethra. Terminal branches of the cavernous nerves are responsible for vascular events during erection and detumescence via innervation of the helicine arteries and trabecular smooth muscle of the penis.[15]

Somatic sensory nerves originate at receptors in the penis and convey sensation of touch, temperature, vibration, and pain. The center for somatic motor nerves is located at Onuf's nucleus in the ventral horn of the S2 to S4 segments. Motor nerve fibers travel along the pudendal nerve to innervate the bulbocavernosus and ischiocavernosus muscles of the penis. The brain has a modulatory effect on the spinal pathways of erection. The regions of the brain specifically involved in penile erection are the medial preoptic area and paraventricular nucleus of the hypothalamus, the periaqueductal gray of the midbrain, and the nucleus paragigantocellularis of the medulla. Likely there are many more neurologic pathways involved in penile erection that have yet to be discovered. In the future, advancements in imaging modalities, such as positron emission tomography and functional magnetic resonance imaging, may allow for improved understanding of central activation during sexual arousal, orgasm, and ejaculation and may help to clarify the pathophysiology triggering sexual disorders, such as psychogenic ED, orgasmic dysfunction, and PE.[21]

Neurotransmitters and Pharmacology of Erection

Neural control of penile erection involves adrenergic, cholinergic, and nonadrenergic-noncholinergic (NANC) neuroeffector systems.[15] In the flaccid state, adrenergic nerves mediate tonic intracavernous smooth muscle contraction, which is the resting state of the penis. This sympathetic contraction is mediated by activation of postsynaptic alpha-1a- and alpha-1d-adrenergic receptors and modulated by presynaptic alpha-2-adrenergic receptors.[22] For penile erection, cholinergic nerves contribute to smooth muscle relaxation through inhibition of adrenergic nerves via inhibitory interneurons and the release of NO from the endothelium by acetylcholine.[23]

The fundamental neurotransmitter that has been identified in penile erection is NO from parasympathetic NANC nerve terminals. NO is released from the cavernous nerves and endothelium of the arterial vasculature. NO activates guanylate cyclase to produce produces cyclic guanosine monophosphate (cGMP) from guanosine triphosphate.[15] cGMP activates G protein–linked cellular processes, leading to decreased intracellular calcium and relaxation of actin–myosin crossbridges in the corporal and arterial smooth musculature. The net effect is arterial vasodilation and increased penile blood flow.[24] Once blood rushes into the sinusoids, shear stress also promotes release of NO from the endothelium, augmenting smooth muscle relaxation and erection. cGMP is broken down by the enzyme phosphodiesterase type 5 (PDE5)

Oxygen tension and substances secreted by endothelial cells lining the sinusoidal spaces, prostaglandins, endothelins, and angiotensin may be involved in penile detumescence.[25] Although mechanisms of action vary, erection-inducing substances cause smooth muscle relaxation, and detumescing agents cause smooth muscle contraction.

Testosterone and Male Sexual Function

A thorough discussion of the relationship between T and erectile function is beyond the scope of this chapter. We will briefly discuss the topic here to be thorough but refer the reader to other chapters in this text for additional information. T levels do not correspond to severity of ED, and T supplementation alone would rarely be utilized as a singular treatment for ED. Lower T levels are associated with low libido and a reduction in the frequency, magnitude, and latency of nocturnal penile erections. However, erectile response to visual sexual stimulation is preserved in men with hypogonadism. This suggests that androgens are not essential for erection.[26]

The importance of normal serum T for the maintenance of male secondary sex characteristics and libido is well established.[4] Low serum T has been associated with a multitude of nonspecific somatic concerns, including fatigue, depressed mood, loss of muscle mass, weight gain, decreased exercise tolerance, and ED.[4] These symptoms are also highly prevalent in middle-aged and older men. The indications and considerations for T therapy are discussed in Chapters 106 and 107. Data are conflicting on whether T supplementation improves response to ED therapy.[26,27]

As men age, there is a progressive decline of such hormones as T, dehydroepiandrosterone, thyroxine, melatonin, and growth hormone, and there is an increase in sex hormone–binding globulin, pituitary gonadotropins, and prolactin.[28] These hormonal changes, in addition to age-related anatomic changes, such as atherosclerosis, penile smooth muscle atrophy, and loss of tissue elasticity, likely both contribute to the increasing incidence of ED as men age.[29]

KEY POINTS

- The penis is composed of the paired corpora cavernosa and the corpus spongiosum, which surrounds the urethra and terminates at the glans penis. Erection is controlled by the sympathetic, parasympathetic, and somatic nervous systems, and neuronal integrity at the brain, spinal cord, and peripheral level is required for modulation of erection. Erection requires a rapid increase in arterial blood flow with resultant compression of venous structures, which reduces venous outflow and maintains erection. The major neurotransmitter involved in penile erection is nitric oxide. Multiple other neurotransmitters, including dopamine, serotonin, oxytocin, and norepinephrine, are also involved with regulation of sexual function.
- Changes associated with aging, such as hormonal changes, atherosclerosis, penile smooth muscle atrophy, and loss of tissue elasticity, contribute to the increased incidence of ED in older men.
- Testosterone levels do not correspond to severity of ED, and studies suggest that androgens are not essential for erection. Lower T levels are associated with low libido and a reduction in the frequency, magnitude, and latency of nocturnal penile erections, but erectile response to visual sexual stimulation is preserved in hypogonadal men.

CLINICAL EVALUATION OF THE MAN WITH ERECTILE DYSFUNCTION

A focused history and physical examination are fundamental for the evaluation of men with complaints of ED. As sexual health can be a sensitive and potentially discomfiting subject, many patients are hesitant to broach the topic with their medical providers.

Discussing Sexual Health with Patients

Patient-reported validated questionnaires, such as the International Index of Erectile Function: Erectile Function Domain (IIEF-EF) or the Sexual Health Inventory for Men (SHIM; Table 109.5), are valuable tools that allow patients to bring sexual concerns to their provider's attention.[30,31] Because these questionnaires were developed with heterosexual intercourse in mind, it is important to understand the context of the patient's sexual relationship when interpreting the results of these tools and ask additional questions as needed. The SHIM is comprised of five questions based on a five-point Likert scale and was derived from the 15-question IIEF, which is a more comprehensive and lengthier instrument developed for use in clinical trials. The SHIM is specifically intended as an office screening tool for ED. Lower scores indicate more severe ED, with classification into five severity grades between no ED (SHIM score 22–25) and severe ED (SHIM score 1–7).

TABLE 109.5 Sexual Health Inventory for Men Questionnaire

Sexual Health Inventory for Men Questionnaire

Over the past 6 months:

1. How do you rate your confidence that you could get and keep an erection?
    1. Very low
    2. Low
    3. Moderate
    4. High
    5. Very high
2. When you had erections with sexual stimulation, how often were your erections hard enough for penetration (entering your partner)?
    0. No sexual activity
    1. Almost never or never
    2. A few times (much less than half the time)
    3. Sometimes (about half the time)
    4. Most times (much more than half the time)
    5. Almost always or always
3. During sexual intercourse, how often were you able to maintain your erection after you had penetrated (entered) your partner?
    0. Did not attempt intercourse
    1. Almost never or never
    2. A few times (much less than half the time)
    3. Sometimes (about half the time)
    4. Most times (much more than half the time)
    5. Almost always or always
4. During sexual intercourse, how difficult was it to maintain your erection to completion of intercourse?
    0. Did not attempt intercourse
    1. Extremely difficult
    2. Very difficult
    3. Difficult
    4. Slightly difficult
    5. Not difficult
5. When you attempted sexual intercourse, how often was it satisfactory for you?
    0. Did not attempt intercourse
    1. Almost never or never
    2. A few times (much less than half the time)
    3. Sometimes (about half the time)
    4. Most times (much more than half the time)
    5. Almost always or always

Score

- 1–7 = Severe ED
- 8–11 = Moderate ED
- 12–16 = Mild to Moderate ED
- 17-21 = Mild ED
- 22–25 = No signs of ED

ED, Erectile dysfunction.

Simple open-ended questions about sexual health may be even more helpful in prompting a conversation about sexual wellness.[31] Facilitating the conversation and letting patients know that it is safe and appropriate to discuss sexual wellness with their providers can alleviate anxiety and give the patient (and possibly the partner) an opportunity to open up about sexual concerns.[32] It is important for healthcare providers in all medical and surgical fields to be comfortable discussing sexual wellness with patients. This is particularity important when a condition or an intervention is being considered that may have sexual health ramifications.[32] Unfortunately, many providers are also hesitant to broach the topic of sexuality with patients.[33] We understand that sexual health need not figure prominently in every patient visit, but we hope to encourage providers to become comfortable with the topic and attentive to the sexual concerns that their patients may have.

History

If the patient expresses an issue with sexual function, it is important to define exactly what his concerns are. Many men will complain of ED but actually have other sexual concerns, such as decreased libido, penile deformity, or PE. ED may be either the cause or the effect of other these sexual problems, such as PE or decreased sexual desire. For instance, a man who lacks desire for sex will typically have difficulty obtaining an erection, and a man who lacks confidence in his erection may engage in vigorous thrusting that leads to rapid ejaculation due to fear of losing his erection.[34] A man with ED may also have reduced sexual interest secondary to performance anxiety.

For men with sexual complaints, a thorough history should include multiple components. First, a medical and surgical history is essential to evaluate the potential roles for medical or surgical conditions as the etiology for ED and to investigate both the organic and psychological causes of ED. A detailed sexual history aimed at determining onset, severity, and duration of ED should also be obtained. Finally, a psychosocial history is also critical, as ED is associated with confidence, self-esteem, relationship quality, and overall quality of life.[35] It is most ideal to define the patient's primary sexual complaint and to focus initial treatment on that specific issue. No matter the etiology or the sexual complaint, erectogenic therapy figures prominently in the management of most male sexual concerns, as the available therapies are efficacious. There is a lack of commonly accessible and approved therapies for many other male sexual concerns. Improved ability to maintain rigid erection typically increases sexual confidence, while other sexual issues, such as PE, Peyronie's disease, and orgasmic dysfunction, are addressed by other means.

ED may be generalized or situational. The context of the sexual relationship is important to determining the most appropriate treatment. For men who do not have a regular partner or those who have multiple partners, inquiry should be directed towards partner-specific differences in erectile response versus erection with masturbation alone. Impaired penile rigidity may be of differing consequence dependent on types of sexual activity. For instance, penile rigidity is less important for masturbation or oral intercourse, more important for vaginal penetration, and even more crucial for anal penetration. Onset of sexual dysfunction should be discussed in addition to any precipitating events, treatments, or conditions such as relationship stress, medical diagnoses, trauma, surgery, or addition of medications.[3,32] In some cases, if the patient has a sexual partner, it is helpful to discuss sexual issues with both partners in order to obtain additional context and to facilitate the candid communication that can be useful in sexual therapy.[36] In other cases, partner involvement may cause patient embarrassment or humiliation. It is notable that improvements in the male partner's sexual function have been associated with improvements in the female partner's sexual function.[37] It is logical that similar parallels would be noted in the sexual function of male partners of men with effectively managed ED.

Physical Examination

A targeted physical examination is important for the evaluation of ED but typically cannot precisely diagnose the etiology of ED or the severity of the condition. A thorough examination may be reassuring to anxious patients, particularly if the provider affords context and explains of the purpose of the various assessments.[3] Vital signs should be obtained, as hypertension is a major risk factor for ED. The patient's general state of being should be assessed for indications of anxiety, depression, and general wellness. Assessment of facial hair and virilization may provide evidence regarding androgen status. Examination of the chest and abdomen may reveal gynecomastia, obesity, ascites, aortic aneurysm, or possibly other findings that point toward an endocrine or metabolic etiology that may contribute to ED or complicate its management.[3] Examination of the penis includes notation of the position of the urethral meatus, circumcision status, presence of scars, and any distinct lesions that may warrant either biopsy or screening for sexually transmitted infection. Examination of the scrotum and testicles can provide information regarding androgen status. Digital rectal examination to assess anal sphincter tone is informative if there is concern for a neurological lesion as a potential cause for ED. Assessment of the bulbocavernosus reflex, which is contraction of the anal sphincter in response to pressure on the glans penis, may also be useful as an assessment of neuropathy. Examination of peripheral pulses and lower extremities may also reveal arterial or venous vascular disease relevant to the ED diagnosis.[3]

Laboratory Testing

Laboratory evaluation of the man with ED is focused on detection of metabolic conditions that may contribute to ED. Fasting lipids, glucose, and glycated hemoglobin should all be evaluated. A basic electrolyte and/or hepatic function panel may be of use for assessment of general health, but does not typically change management of ED.[3] The 2018 AUA guidelines on management of ED recommend assessment of morning T levels in all men presenting with ED.[4] Men with bothersome sexual symptoms in addition to low T as determined by the established reference ranges[38] should undergo repeat testing, including early morning serum T, luteinizing hormone, and prolactin.[4] The decision of whether to supplement T should be made after careful consideration of the risks and benefits of T treatment for each individual patient.[4] T treatment alone is rarely adequate to treat ED, but normalizing serum T may improve patient response to other pharmacologic treatments specific for ED.[39]

Specialized Testing for Erectile Dysfunction (Table 109.6)

The **combined injection and stimulation test (CIS)** is a valuable augment to the physical examination in many men who have complaints of ED. Typically, this test is reserved for patients who are not responding to oral agents for ED or those who have concerns about penile deformity. It is valuable to describe the process for the patient prior to proceeding, as anxiety about the process may inhibit the erectile response through mechanisms discussed previously. For this test, an erectogenic medication, typically a combination of papaverine and phentolamine and/or prostaglandin E1, is injected into the penis in the clinical setting. The type of medication and the dosage is selected contingent on the suspected etiology of the disorder. The patient's erectile response allows for an assessment of the arteriogenic, venogenic, and possibly psychogenic etiologies of ED, in addition to

TABLE 109.6 Specialized Tests That May be Helpful in the Evaluation of Erectile Dysfunction Patients

Test	Indications
Combined injection and stimulation test (CIS)	• Assesses penile vascular function and presence of penile deformities with erection • Allows for correct dosing and concentration of medication for men who choose ICI therapy for ED
Penile duplex ultrasonography (PDU)	• Allows for same as CIS, which is part of the PDU process • Assesses arterial inflow and venoocclusive function of the penis • Assesses internal anatomy of the penis to evaluate vessels for calcification, corpora and septum for fibrosis, and tunica for plaque formation or calcification
Cavernosometry and cavernosography*	• Assessment for congenital or traumatic venous leakage in men with venoocculsive ED
Selective internal pudendal pelvic arteriography*	• Assess for the presence of focal arterial lesions in men with arterial ED on PDU • Typically reserved for very young men with a history or traumatic ED
Ambulatory nocturnal penile tumescence and rigidity*	• Assess nocturnal erectile responses • Historically used to differentiate psychogenic from organic ED • Unreliable

*Denotes that this test is rarely used in contemporary practice.
ICI. Intracavernosal injection; *ED,* erectile dysfunction.

allowing for physical examination of the rigid penis, which may reveal penile deformities. CIS facilitates a more thorough discussion of the etiology/etiologies of ED and may help to guide additional medical therapy or suggest instances when surgical therapy would be most effective.

Penile color duplex ultrasound (PDU) is considered by many to be the gold-standard assessment for ED due to its ability to provide functional hemodynamic data, but in most cases it does not change the management of ED. In addition, the quality of PDU is exceedingly operator-dependent, and studies show that many patients may need repeated testing (i.e., repeated penile injections or even additional clinic visits) in order to fully evaluate their complaints.[40] With these issues in mind, PDU is best conducted in high-volume centers by examiners with extensive training and experience in conducting and interpreting the study.

PDU does have utility in specific clinical situations. It is best reserved for patients in whom the results may change the management strategy, such as in young men with a history of severe pelvic trauma or lifelong, severe ED. In some cases, PDU may suggest cases in which medical therapy is unlikely to succeed. Patients with very poor response to penile injection or with poor hemodynamic parameters on PDU may be counseled that they are unlikely to succeed with medical ED therapy; such men may consider more rapid selection of invasive ED therapy. Most patients and urologists are likely to agree, however, that a trial of medical therapy is warranted prior to launching into irreversible surgical interventions, regardless of what the PDU reveals. In addition to being a valuable diagnostic tool for some men, PDU may also have therapeutic value in a certain subset of men with ED who value knowing exactly what the anatomic or psychological basis for their condition may be.

Standard operating procedures for the performance and interpretation of PDU are available from knowledgeable clinicians.[41] PDU is most commonly performed in several steps—on the flaccid penis, after injection of vasodilators, and finally after self-stimulation to erection—to assess blood flow in the cavernous arteries. The most important hemodynamic parameters are peak systolic velocity (PSV) and end diastolic velocity (EDV) of the rigid erection. A PSV of greater than 30 cm/s is generally considered normal. Arterial flow of less than 25 cm/s is considered evidence of arterial insufficiency.[41] Resistive index (RI) is a derived variable ([PSV– EDV]/PSV) that is used to assess the presence of venous leak or venooclussive disease; RI of 0.6 or less is consistent with corporal venous leakage.[41] In addition, PDU assesses the echogenicity of the spongy tissue to evaluate for corporal fibrosis and for plaques of the tunica albuginea that might suggest of Peyronie disease.[41,42]

Biothesiometry is sensory testing that may be utilized in patients who have concerns about decreased penile sensation. Most often, a handheld, electromagnetic, adjustable, vibrating device known as a biothesiometer is utilized, but other modalities such as heat/cold or sharp/dull or soft/hard may also be employed. The stimulus is applied to the glans penis and both sides of the penile shaft and with varying degrees of intensity. For vibratory stimulus, the minimum vibratory intensity that is detectable to the patient is assessed. These values are compared with the sensitivity of other skin regions, most commonly the pulp of the fingertips and big toes bilaterally.[43] Penile thermal sensory testing may be performed to quantify conductance of small sensory nerves, which may reflect autonomic disturbances in the context of diffuse neuropathy. Although biothesiometry may be informative, it seldom leads to a change in management. It may, however, prompt further evaluation and possibly the need for neurology consultation.

Cavernosometry with or without **cavernosography** is rarely utilized, due to invasiveness and lack of clinical applicability in most cases of ED. These tests require injection of an erectogenic agent followed by assessment of real-time ICP during saline infusion into the penis. Important metrics include ICP and flow rate needed to maintain erection. Lower pressure and higher flow rate are indicative of venous leak as the etiology of ED. If contrast infusion is performed, fluoroscopic images or even computed tomography scan can be obtained to evaluate for venous leakage. It is essential that maximal penile erection be obtained for accurate assessment of leakage.[44] Diffuse leakage of contrast is the most common finding in older men with diabetes or other conditions leading to tissue senescence, and this is not amenable to surgical repair. Rarely, a young man with ED may have a discrete area of venous leakage from the corpora cavernosa and may be considered a candidate for a venous ligation procedure. However, this intervention that is not supported by the current AUA guidelines on ED.[3]

Selective internal pudendal angiography (SIPA) may be indicated in the case of a young man with a history of ED after pelvic trauma with a unilateral or bilateral cavernosal PSV on PDU that is below expected thresholds. In select cases, SIPA may reveal a focal occlusion of the pudendal or more distal arteries that is potentially amenable to bypass for penile revascularization.[45] This procedure should only be performed in centers of excellence with highly experienced surgeons after meticulous patient selection.

Various other tests, including a variety of reflex and autonomic nervous system tests, have been promoted for assessment of penile erection response; examples include bulbocavernosus reflex time, sympathetic skin response, pudendal somatosensory evoked potentials, and cavernous electromyography. At this time the clinical utility of these examinations is unclear.[46]

KEY POINTS

- History and physical examination should focus on the various etiologies (psychogenic and organic) of ED. Validated questionnaires may be useful clinical tools to initiate a discussion about sexual dysfunction, especially for patients who are embarrassed or uncomfortable with the topic. In addition to obtaining a thorough history, assessing vital signs, and performing a thorough physical exam, consider ordering labs, such as fasting lipids, glucose, HbA1c, basic renal and/or hepatic function panel, and early morning testosterone levels, to evaluate for medical conditions associated with ED.
- If clinically indicated, there are many specialized tests, including combined injection and stimulation test, duplex ultrasonography, biothesiometry, cavernosometry/cavernosography, and selective internal pudendal arteriography, that a specialist may offer to further evaluate the severity and etiologies of ED.

TREATMENT OF ERECTILE DYSFUNCTION

The patient's baseline state of health, relationship status, objectives for treatment, and threshold for risk must all be considered when discussing treatment options for ED. Each man will have his own preferences regarding how to treat ED, and it is best to outline the treatment options to allow for an informed, shared decision.[3] As part of the ED treatment discussion, men should be counseled on how other medical conditions may contribute to the condition. Comorbid conditions that are detected during ED evaluation, such as obesity, diabetes, hypertension, hyperlipidemia, and arterial vascular disease, should be appropriately managed by the diagnosing physician or referrals placed to consultants, such as nutrition, cardiology, endocrinology, neurology, bariatric surgery, or vascular surgery.[3]

The Princeton III guidelines provide recommendations regarding management of ED in light of cardiovascular risk.[47] Patients who are deemed high-risk for cardiac events, such as those with unstable angina, high-risk arrhythmia, severe congestive heart failure, myocardial infarction within the past 2 weeks, and severe cardiac valve disease, should have stabilization of their cardiac status before engaging in sexual activity. Intermediate-risk patients, such as men with noncardiac vascular disease, including peripheral artery disease or history of transient ischemic attack, mild to moderate angina, moderate congestive heart failure, or other conditions that portent moderate cardiac risk, may consider cardiac evaluation before engaging in sexual activity or receiving treatment for ED.[47]

Adaptive Sexuality

Some patients may not be candidates for medical or surgical therapy for ED due to medical or surgical comorbidities, or simply personal preference. Many of these patients can maintain a satisfying sexual life by adapting their sexual practices to accommodate the absence of rigid penile erections.[3] Alternative sexual activities, such as mutual masturbation, oral sex, or anal stimulation, may be satisfying options for some couples if penile rigidity is insufficient for coital intercourse. Use of assistive devices, such as vibratory stimulators or lubricants and receptive devices, and may also be valuable adjuncts for some couples.[48] For patients with physical limitations that make the act of intercourse challenging, there are special positioning devices that may augment sexual encounters to improve mechanics and sexual satisfaction. For patients who are interested in exploring adaptive sexuality, referral to a sex therapist is recommended. Sex therapists are behavioral health specialists trained to educate patients and their partners and to facilitate development of a satisfying sexual relationship tailored to patient goals and limitations.

Lifestyle Modification

Men with ED should be counseled on the importance of healthy lifestyle in terms of diet, nutrition, activity, body weight, and sleep. The Massachusetts Male Aging Study revealed that men who are sedentary are at greater risk of ED than men who are active, as well as men who are sedentary but become physically active.[49] This study also identified that the risk factors for ED are very similar to those of cardiovascular disease (CVD), including diabetes, smoking, and dyslipidemia. With this in mind, ED should be considered at the very least a marker for possible further vascular disease in all men. Men with new-onset ED and no signs or symptoms of CVD are at increased risk of a cardiovascular event in the subsequent 3 to 5 years.[50] The presentation of a *young* man with ED gives the clinician an opportunity to assess for CVD and to discuss prevention as well. Men in their 40s with ED have a 50-fold increased risk of CVD, and men in their 20s and 30s have a 7-fold increased risk.[51] Atherosclerosis affects all vascular beds equally, but smaller arteries are more likely to become occluded than larger vessels. As penile arteries are only 1 to 2 mm in size, and coronaries are larger (3–4 mm), penile arteries may serve as a sensitive indicator for consequent development of CVD.[52]

Although positive lifestyle changes are challenging to implement, and even more challenging to maintain in many cases,[3] the possibility of improving sexual response may be a powerful motivator for some men and their partners. Robust evidence demonstrates that men who are sedentary and/or obese are at greater risk for ED compared with men who are active and of normal body weight.[53] A randomized trial of men with metabolic syndrome revealed that intensive lifestyle change, including exercise and reduced intake of processed, high-fat foods, improved metabolic parameters and produced a clinically significant improvement in erectile function as measured by the SHIM.[54] Furthermore, a systematic review of studies on exercise for ED intervention revealed that a supervised program of at least 40 minutes of moderate to vigorous physical activity four times a week was associated with meaningful improvements in erectile function.[55]

Mental Health

Mental health plays a central role in male sexual wellness. Mental distraction inhibits the ability of the man to fully engage in sexual relations. Interpersonal issues with partners may be the primary precipitating factor in some cases of ED, but other factors such as depression, anxiety, adjustment disorders, or medications taken for these conditions may also contribute to male sexual dysfunction.[56] Psychological stress frequently leads to a physiologic stress response that involves activation of the sympathetic nervous system, peripheral vasoconstriction, and inhibition of penile erection. Explaining the biologic basis for ED associated with psychological conditions may be therapeutic for some men and for their partners.[14] Even in men for whom psychological or interpersonal issues are not the primary cause of ED, anxiety over sexual performance may perpetuate ED via the same biologic mechanism.[56] If sexual partners interpret ED as a lack of interest in the relationship or as a sign of infidelity, this may further exacerbate the existing heightened adrenergic tone and worsen the overall condition.

Human sexuality is complex, and it is common for human beings to have deep-seated psychological issues relating to sexual expression. Considering that a sexual relationship typically involves two, or more, individuals who may have distinct sexual concerns, sex therapy or counseling can be an integral element in ED management. Mental health interventions can be valuable as primary therapy[57] in some cases or as an adjunct to medical or surgical therapy for ED.[58] Referral to behavioral health consultants, including sex educators, counselors, and therapists, with expertise in mental health and sexual wellness is

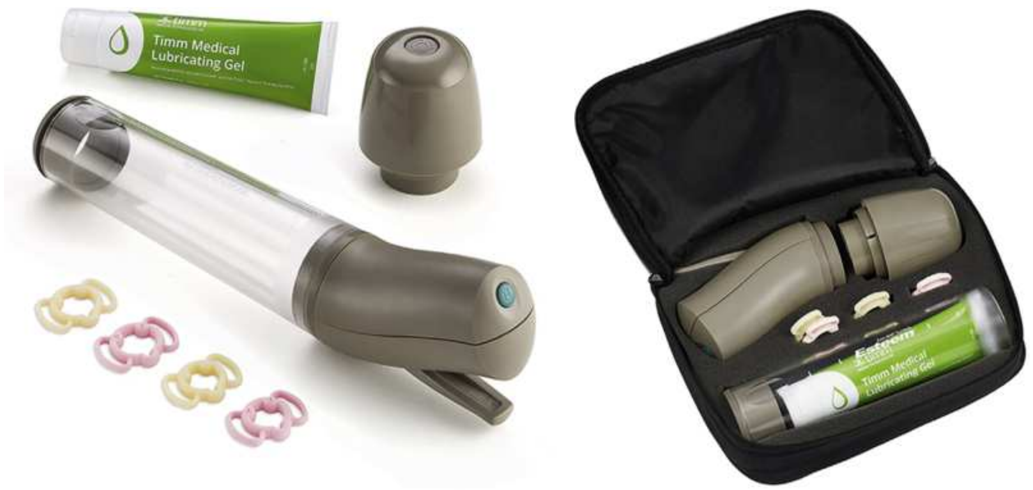

Figure 109.2 Osbon Esteem Manual Vacuum Therapy System manufactured by Pos-T-Vac Medical.

a low-risk intervention with the potential to educate about sexuality and sexual response, which is extremely valuable for most patients and their partners.

Vacuum Erection Device

Vacuum erection device (VED) therapy is a low-risk, nonpharmaceutical, nonsurgical option for management of ED. VED can be utilized in nearly all etiologies of ED and may be used as monotherapy or in combination with PDE5 inhibitors or intracavernosal injection to augment the erectogenic effects of these medications. These devices are cylindrical in shape to fit over the phallus and are designed to create a vacuum around the penis using either a hand-driven or electronic pump. This negative pressure draws venous blood into the corpora cavernosa, leading to engorgement, and in some cases turgidity.[59,60] To maintain the erection, a constrictive ring can then be placed at the base of the penis to prevent outflow from the penis (Fig. 109.2). The combination of VED and constrictive ring restores adequate rigidity for some men,[59] but others may find that it is cumbersome, uncomfortable, or embarrassing, or that the ring does not fit well due to body habitus. Some patients may find the VED-induced erection unstable, uncomfortable, cold, or of insufficient rigidity to facilitate penile intromission.[61,62] Minor risks include petechiae, bruising (particularly in anticoagulation patients), skin edema, or penile discomfort. Constrictive rings are generally safe for short periods (30–60 minutes), but severe penile tissue damage from ischemia can result if left in place for prolonged periods of time. VEDs have efficacy rates approaching those of PDE5Is and intracavernosal injection but also have low overall acceptance and high long-term discontinuation rates.

VEDs may also be recommended as a component of erectile preservation programs for patients who have had radical pelvic surgery or surgery for PD. Clinicians theorize that VED use may prevent penile shrinkage after pelvic surgery and potentially prevent PD occurrence after pelvic surgery and recurrence after penile surgery for Peyronie disease. For postsurgical patients, VEDs are frequently used in concert with oral agents, intracavernosal injection therapy, or transurethral therapies for ED.

MEDICAL THERAPY FOR ERECTILE DYSFUNCTION

In 1998, the management of ED was transformed by the introduction the first highly effective, safe oral pharmacotherapy (sildenafil) for ED.[63] This revolution not only improved access to care for ED management by allowing primary care providers to treat ED, it also changed public perception about the medical condition itself and allowed the topic to be discussed openly in various forums, particularly in mainstream media. The resulting cultural impact of oral pharmacotherapy for ED has been virtually unparalleled by any other medication in recent years. This phenomenon has encouraged additional research and development of other options for the treatment of ED.

Herbal Supplements and Complementary Medicine

Over the past two decades or so, there has been a boom in both the production and mass marketing of products and procedures targeted at men with ED. For various reasons, including skepticism about pharmacotherapy, cost, and embarrassment, many patients are enthusiastic about “natural remedies,” such as acupuncture, herbal supplements, nutraceuticals, and other nonprescription treatments, for ED. As the population of men with ED tends to be vulnerable, and in many cases desperate for an effective treatment, it is important that providers understand what products are being marketed in order to protect patients from potential harm.

Unfortunately, manufacturers of supplements and nutraceuticals are able to make expansive claims about efficacy in the absence of evidence by providing a general disclaimer statement on the product label.[64] In addition, the production of supplements is not closely regulated, and the safety, content, and quality vary substantially among herbal supplements sold by different manufacturers.[65] Most troubling, some “natural” therapeutics may be contaminated with pharmaceuticals, including prescription ED medications or similar compounds, posing serious risk to individuals with certain medical conditions.[66] Most of the trials investigating the utility of herbal formulations have been small, poorly designed studies.[67]

Korean red ginseng is the supplement with the most robust data on efficacy in ED. Even so, this is based on a few small, randomized controlled trials with inadequate sample sizes and methodological quality too low to draw definitive conclusions.[68] Yohimbine, derived from the bark of the yohimbe tree, has been used for many years to treat ED, specifically in the era prior to widespread commercial availability of the PDE5 inhibitors. Yohimbine functions as an alpha-2-adrenergic receptor antagonist. Some small studies have suggested that yohimbine is superior to placebo for the treatment of ED, including a 1998 metanalysis,[69] but the AUA guidelines panel concluded that there were insufficient quality data to recommend yohimbine as a standard treatment for ED.[3]

L-arginine, a precursor of NO, has been studied for use in ED. A recent double-blind, placebo-controlled study of 124 men aged 30 to 50 years of a commercial L-arginine product revealed a significant improvement in SHIM score.[70] Because the improvement was so dramatically different than findings from previous similar trials, however, it was determined that additional larger trials with large sample size and rigorous methodological quality are needed.

Acupuncture has been used for centuries for a variety of medical conditions, and more recently it has been employed for ED. A recent metanalysis of 22 randomized clinical trials, with 14 focused on psychogenic ED, reported that there is low-quality evidence showing a beneficial effect of acupuncture as an adjunct to other treatments for ED, including oral medications and oral herbal supplements, for patients with mainly psychogenic ED.[71] Most of the trials were identified to have small sample sizes and high or unclear bias.

Phosphodiesterase Type 5 Inhibitors

Oral therapy for ED focuses on the NO pathway. Currently, PDE5 inhibitors are the only class of orally bioavailable medications commercially available and approved by the US Food and Drug Administration (FDA) for the management of ED. These drugs inhibit the breakdown of cGMP by PDE5 to perpetuate the NO cascade.[72] All four PDE5 inhibitors that are commercially available (avanafil, sildenafil, tadalafil, and vardenafil) in the United States are highly efficacious for management of ED. There are additional oral agents available in other countries.

It is important that patients understand that PDE5 inhibitors alone do not produce penile erection, as they do not alone increase production of cGMP. Sexual stimulation to arouse the erectile response must be present in order for PDE5 inhibitors to have an effect. Men who take a PDE5 inhibitor and do not engage in erotic stimulation are not likely to have much response.[73] Likewise, men whose primary concern is decreased libido may find their response to PDE5 inhibitors suboptimal. Finally, men who have impaired NO responses secondary to cavernous nerve damage or advanced endothelial and neuronal injury from medical conditions tend to respond poorly to PDE5 inhibitors.[74]

Contraindications to the use of PDE5 inhibitors are relatively few and mostly relate to CVD. Most importantly, PDE5 inhibitor use in combination with nitrates has the potential to induce severe hypotension. PDE5 inhibitors are contraindicated for patients taking stable nitrate therapy.[75] For patients who utilize nitroglycerin as needed for angina pectoris, PDE5 inhibitors may be prescribed at the discretion of the provider after a thorough discussion about avoiding the medication within 24 to 36 hours of a PDE5 inhibitor. For these patients, topical nitroglycerin may utilized in the emergency setting as needed, as it is easily reversed if severe hypotension develops. Hypotension has also been reported in men using PDE5 inhibitors concomitant with alpha-adrenergic blockers, and dosing should be separated by at least 4 hours.[75] PDE5 inhibitors rarely cause priapism in otherwise healthy patients. The risk of priapism may be higher in patients who use these medications in conjunction with recreational or certain prescription drugs.[76]

All currently available PDE5 inhibitors are metabolized via the cytochrome CYP3A4 system. For this reason, CYP3A4 inhibitors, such as cimetidine, erythromycin, ketoconazole, itraconazole, and protease inhibitors (such as indinavir, ritonavir, and saquinavir), may lead to elevated serum levels of PDE5 inhibitors.[77,78] Lower dosages of PDE5 inhibitors in men using these CYP3A4 inhibitor medications may be considered.[79]

PDE5 inhibitor treatment has been linked to of various conditions, including vision loss from nonarteritic ischemic optic neuropathy (NAION),[80] hearing loss, melanoma, and prostate cancer recurrence. There is epidemiological evidence to support an association of PDE5 inhibitor use and some of these conditions, particularly NAION.[81] Causality remains unclear in many of these cases, and the magnitude of increased absolute risk for any of these conditions appears to be very low. Men who have or are at particular risk of these conditions should be counseled about the relative risks and benefits of PDE5 inhibitors prior to initiating therapy.[81]

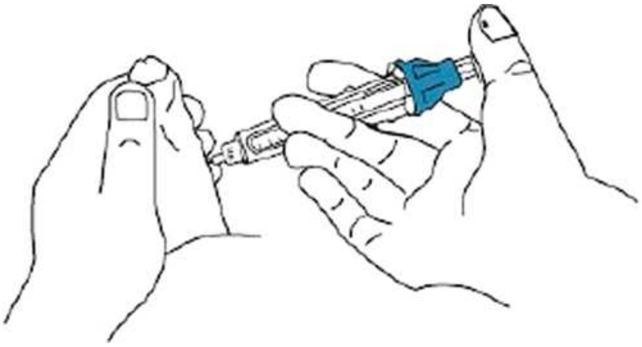

Figure 109.3 Intracavernosal injection into the lateral aspect of the penile shaft for erectile dysfunction. (From the Edex package insert.)

The most common side effects of PDE5 inhibitors are related to vasodilation and include headache, dizziness, flushing, nasal congestion, and dyspepsia. Other side effects are blue-tinted vision, back pain, myalgia, and limb pain. Depending on the drug and the dosage, the incidence of side effects from PDE5Is ranges from 8.5% to 25.1%.[82]

Sildenafil. Sildenafil citrate (Viagra, Pfizer), the first commercially available PDE5 inhibitor, has a half-life of 4 hours and reaches peak serum concentration 60 minutes after dosing. Absorption in the bowel is slowed and the peak serum concentration reduced when taken with high-lipid foods. Sildenafil should ideally be taken on an empty stomach 30 to 60 minutes prior to sexual stimulation. It is available in 25-, 50-, and 100-mg doses for the management of ED.[78]

Vardenafil. Vardenafil hydrochloride (Levitra, Bayer/GlaxoSmithKline) has a half-life of 4 to 5 hours and reaches peak serum concentration 60 minutes after dosing. Like sildenafil, vardenafil should ideally be taken on an empty stomach.[77] Vardenafil is available in 5-, 10-, and 20-mg doses. A 10-mg sublingual dissolving formulation of vardenafil (Staxyn, Bayer/GlaxoSmithKline) is available and is less affected by food intake compared with the oral tablet formulation. Half-life of the sublingual vardenafil is 4 to 5 hours, but time to peak serum concentration is 90 minutes. Absolute contraindications to vardenafil are congenital QT syndrome and class IA or III antiarrhythmics.[77]

Tadalafil. Tadalafil (Cialis, Lilly/ICOS), with a chemical structure distinct from the other PDE5 inhibitors,[83] has a half-life of 18 hours and reaches peak serum concentration 2 hours after dosing. Absorption is not influenced by food intake. Tadalafil is available as 5-, 10-, and 20-mg on-demand tablets. In addition, a once-daily dose of tadalafil 2.5- and 5-mg is available for management of lower urinary tract symptoms and may be useful for ED patients who have side effects with higher dosages of other PDE5 inhibitors. After 5 days of once-daily dosing, steady-state serum drug levels are obtained and are roughly proportional to 60% higher than the daily dose.

Avanafil. Avanafil (Stendra, Mist Pharmaceuticals/TIMM Medical), a pyrimidine carboxamide PDE5 inhibitor,[84] has a half-life of 5 hours and reaches peak serum concentration 30 to 45 minutes after dosing. Avanafil should be taken on an empty stomach, particularly with respect to fatty foods, to avoid slowed absorption and reduced peak concentrations.[84] It is available as 50-, 100-, and 200-mg on-demand doses.

Other Phosphodiesterase Type 5 Inhibitors. Multiple other PDE5 inhibitors have been approved for the management of ED outside of the United States. Examples include lodenafil, mirodenafil, and udenafil.[85-87] The efficacy and side effect profile of these drugs appear generally similar to the other PDE5 inhibitors previously discussed.

Intracavernosal Injection Therapy

In the late 1970s, scientists discovered that penile erection could be induced by direct injection of vasodilators into the corpora cavernosa.[88] Subsequently, in 1983, Dr. Giles Brindley administered papaverine to himself and subsequently displayed his erect phallus to all attendees at a national urological conference.[89,90] Ever since, injectable agents have been a mainstay of ED evaluation and management. Penile injections are a particularly important option for men who PDE5 inhibitor nonresponders and for those who are not candidates for PDE5 inhibitors.[91]

Prostaglandin E1 (alprostadil, marketed under the trade names CaverJect[92] [Pfizer] and Edex[93] [Endo Pharmaceuticals, Inc]) is the only FDA-approved injection agent for intracavernosal injection (Fig. 109.3). It is typically dosed at between 10 and 40 mcg and is manufactured in a vial along with a prepackaged delivery system.[94] Papaverine, a nonselective PDE5 inhibitor, and phentolamine, an alpha-blocker, are also frequently utilized as injectable erectogenic agents. Atropine, an anticholinergic, has been employed for intracavernosal therapy, but less often. Most commonly, these medications are compounded into mixtures of several drugs, named generically as “bimix,” “trimix,” or “quadmix,” depending on the number of component drugs. Most commonly, “bimix” refers to mixtures containing papaverine and phentolamine, whereas “trimix” refers to mixtures containing papaverine, phentolamine, and prostaglandin E1.[95] “Quadmix” would include atropine as the additional agent. The compounded medications generally cost less and can be concentrated to produce greater efficacy at lower doses of each individual component, reducing the risk of side effects and decreasing the volume of medication required. A test dose should be performed in the clinic along with self-injection teaching and demonstration of proficiency prior to at-home use.

Patients may express apprehension about the penile self-injection, but discomfort from the actual injection is rare, as the needle used is most often 30 gauge or smaller. On the other hand, men may experience discomfort from the injected agent itself, with approximately 15% to 30% of men experiencing penile pain with prostaglandin E1 injection. Petechiae and bruising may occur with self-injection of any agent, but compression at the injection site for a brief period of time (5 minutes) after injection reduces the risk of bleeding. A longer period of compression (7–10 minutes) is necessary for patients who have clotting disorders or take anticoagulant therapy. The risk of priapism with injectable agents is significant, and patients should be counseled to start at a low dose and titrate in small increments to obtain an erection satisfactory for their sexual goals. If satisfactory results cannot be obtained with a given prescription, a more concentrated mixture or one that includes additional vasoactive drugs (e.g., escalation from bimix to trimix to quadmix) may be considered. Typical volumes of medication utilized for intracavernosal injection are small, between 0.1 and 1 cc. If additional volume is required, frequently the provider will order a more concentrated medication.

Besides priapism, the major risks with repeated intracavernosal injections and/or the injectable agents themselves are corporal scarring, progressive fibrosis, and possibly penile deformities such as Peyronie disease. Whether these conditions occur in response to the therapy or are due to natural progression of ED is unclear. Men should alternate the side of injection and the location along the shaft at which the injection is administered and firmly compress the injection site after each injection (5–10 minutes) to minimize these potentially devastating conditions. Physical examination after 3 to 6 months of therapy should be performed to identify these conditions early and to potentially modify technique or withdraw therapy as needed.

Urethral Prostaglandin Suppositories

Medicated Urethral Suppository for Erections (MUSE, Meda Pharmaceuticals[96]) is a urethral suppository containing PGE-1 (Fig. 109.4). MUSE, available in doses of 125, 250, 500, and 1000 mcg, causes corporal arterial vasodilation after absorption through the urethra into the corporal bodies.[97] Side effects may include urethral discomfort, penile pain, and mucous membrane irritation in sexual partners. Due to the potential risk of syncope, it is recommended that a test dose be applied in the clinic prior to at-home use. The most common adverse event with MUSE is genital pain, with pain in the penis, urethra, or testes reported in some men.[96] Typically, the pain is transient and mild, but it may be more severe in patients after pelvic nerve injury, such as after prostatectomy or cystectomy.

SURGICAL THERAPIES FOR ERECTILE DYSFUNCTION

The 2018 AUA guidelines on ED affirm that properly informed patients may elect to proceed immediately to surgical therapy for ED if desired.[3] Surgery may certainly be considered first-line intervention in men with severe vascular disease or ED related to radical pelvic surgery. Most often, however, clinicians recommend gradual escalation in therapy from least to most invasive, choosing to initiate therapy with an oral PDE5 inhibitor then progress to second- and third-line medical options, and finally to surgery if all other options fail. Prosthesis surgery is irreversible—the corporal tissue is permanently altered, such that physiologic erection is no longer possible without the device. The penile prosthesis is the mainstay of surgical treatment for ED, and there are two classes of penile prostheses: malleable and inflatable.

Malleable Penile Prostheses

Malleable, or semirigid, penile implants are most commonly composed of two symmetric, malleable (noninflatable) cylinders made of silicone with a central intertwined metallic bendable core. One cylinder is placed within each corpus cavernosum (Figs. 109.5 and 109.6). Another of these devices is made of a silicone rubber sheath containing (*Used with the permission of Coloplast A/S.*)rod column, which provides rigidity when the rings are lined up in a straight line and flaccidity when the penis is bent (Fig. 109.7). The advantages of all types of malleable implants are that they are easy to implant, easy to operate, and durable, as they lack mechanical parts that may break. These are also considerably cheaper than the inflatable devices, making them a popular option for patients with limited insurance coverage or resources. Besides the usual risks of penile implant (bleeding, infection, and urethral or crural perforation), the greatest risk of malleable implants is the risk of distal tip erosion into the glans penis. This may be a consequence of oversizing the device or of patient vascular disease. Additional disadvantages are that the device may interfere with urination in some cases and may be difficult to conceal under clothing. Possible candidates for malleable devices may be patients without the manual dexterity to manipulate the pump of an inflatable device, patients who desire penile rigidity for fit of a condom catheter, or patients who desire minimal complexity.

Inflatable Penile Prostheses

Inflatable penile prostheses are hydraulic devices that account for approximately 85% of the US market. These devices may have two components and or three components, with the distinction being the presence or absence of a reservoir for storage of fluid that is shifted into two inflatable cylinders placed inside the corpora cavernosa.[98]

A **two-piece inflatable prosthesis** consists of a pair of inflatable cylinders attached to a scrotal pump (Fig. 109.8). The reservoir for the fluid is in the proximal portion of the cylinders. The prosthesis is activated with the pump in the scrotum and deflated by manually bending the penis at the midshaft. These devices do permit the appearance of improved flaccidity versus the malleable implants, but there is limited detumescence that can be attained, as there is no separate reservoir to contain the fluid. The two-piece device may be considered a compromise between the ease of use of the malleable device and the potential for expansion of the three-piece device.

The **three-piece inflatable prosthesis** can be considered the gold standard for surgical treatment of ED (Figs. 109.9 and 109.10). These devices again have paired penile cylinders and a scrotal pump, but they also have a reservoir for saline that is placed in the retropubic space or posterior to the abdominal wall fascia. The advantages of three-piece prostheses are excellent rigidity when erect and a natural appearance when flaccid. These devices have high patient and partner satisfaction rates, in excess of 90%, and tend to be durable, with mean lifespans of 10 to 15 years.[99,100] The most feared, and most devastating, complication of penile implant surgery is infection. Modern prostheses incorporate antibiotic impregnation and elution, and in the hands of high-volume surgeon, infection rates are less than 2% for virgin implants.[101] Poor short-term blood glucose control has been associated with a higher risk of infection.

Careful patient selection, expectation management, and meticulous preoperative counseling are essential for optimal outcomes with all types of penile prostheses. Risks include mechanical failure, cylinder or tubing leaks, reservoir herniation, palpable tubing, perforation, persistent penile or pelvic pain, and autoinflation. Patients may also be disappointed with their erection length or girth after prosthesis placement. This can be estimated preoperatively for the patient in the clinic based on the stretched penile length in the flaccid state. The size of the device implanted is specific to the measured length of the corpora cavernosa at the time of implantation. Additionally, the glans penis does not erect with the penile prosthesis, and some patients may find this disappointing. Finally, postoperatively it may take a significant amount of time for the patient and his partner to become comfortable operating the implant. Close follow-up will help to mitigate these postoperative concerns.

Penile Vascular Surgery

Penile vascular surgery is rarely indicated for management of ED, and it is rarely effective, except in very select patients. With this in mind, we recommended that patients who may be candidates for penile vascular surgery be referred to high-volume centers. In 1902, dorsal vein ligation was first introduced as the earliest contemporary surgical approach to ED. In the 1970s, penile arterial bypass surgery was reported as a treatment for ED. In the 1980s, venous surgery was reintroduced with modifications for the treatment of venoocclusive dysfunction. The current AUA guidelines for ED management suggest that the only patients who may be candidates for arterial vascular surgery are young healthy men, without generalized vascular disease or venoocclusive dysfunction, who have focal pelvic or penile arterial occlusion. Even in these patients, penile prosthesis placement may be the surgical treatment of choice. The AUA guidelines recommend against venous surgery.[3]

Arterial Surgery for Erectile Dysfunction. Though rarely discovered, isolated stenosis or focal occlusion of pelvic or penile arteries may be amenable to surgical repair. Arterial revascularization surgery for these patients could allow for the restoration of erectile function without the need for medications, injections, or devices. Arterial reconstructive surgery is a treatment option reserved for healthy young men (usually aged 55 years or younger) with acquired ED secondary to focal arterial occlusion, typically secondary to trauma, and in the absence of severe venoocclusive disease or generalized vascular disease.[102] Most frequently, however, penile arterial insufficiency is the result of generalized arteriosclerosis associated with medical conditions such as cigarette smoking, diabetes mellitus, hypercholesterolemia, and hypertension. For patients with these conditions, arterial revascularization is not a surgical option, because diffuse small vessel disease is present.

Penile arterial insufficiency is best diagnosed by performing a CIS test followed by self-stimulation. Physical exam and PDU can then be performed to evaluate for rigidity and duration of erection in addition to arterial flow velocity and venoocclusive function. If ED secondary to arterial insufficiency is confirmed, selective pudendal/penile arteriogram can be performed to evaluate penile vascular anatomy and to identify the location of any specific arterial lesion. The most commonly used technique for penile arterial vascular surgery is to bypass the occlusion by bringing the inferior epigastric artery to either the dorsal penile artery (revascularization) or to the deep dorsal vein (arterialization). The most frequent side effect with penile arterialization is glans hyperemia, with other complications being infection, hematoma, and thrombosis of the anastomosis. Long-term results in these patients are highly variable.

TABLE 109.7 Terms Frequently Encountered in Sexual Medicine

Anorgasmia is the inability to achieve an orgasm during conscious sexual activity, although nocturnal emission may occur.

Premature (rapid) ejaculation refers to persistent or recurrent occurrence of ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it.

Retarded ejaculation is undue delay in reaching a climax during sexual activity.

Retrograde ejaculation denotes backflow of semen into the bladder during ejaculation owing to an incompetent bladder neck mechanism.

Priapism is a prolonged erection that continues beyond or in the absence of sexual stimulation. Priapism is often painful and is considered a urologic emergency. Any erection that lasts longer than 4 hours requires urgent medical evaluation.

Peyronie disease is a fibrotic condition of the tunica of the corporal bodies of the penis that causes plaque (scar) development with subsequent penile curvature or other deformity, such as indents or hourglass deformities, of the erect penis.

Venous Ligation Surgery. Penile venous surgery is not recommended by the AUA guideline for the management of ED.[3] However, there are instances in which venous surgery may be considered in young patients with clearly defined and visualized venous leakage. Venogenic ED may be suspected in a young man who has congenital ED or posttraumatic ED. These men will typically have robust arterial inflow (>25 cm/sec) as measured by PDU, but physical exam reveals rapid resolution of erection, and PDU reveals an end-diastolic flow of greater than 5 cm/sec, signifying venous leak. The confirmatory test for the diagnosis of venous leak is dynamic infusion cavernosometry (DICC), as previously discussed. DICC requires injection of an erectogenic agent and infusion of saline to maintain an erection. An abnormal results requires a flow of more than 10 cc/minute to maintain the erection or a drop of ICP greater than 50 mm Hg within 30 seconds of infusion termination. Cavernosogram can then be used to visualize the location of the venous leakage of radioopaque contrast.

Results of penile venous surgery are mixed, and there is unanimous agreement that only young men with congenital or traumatic venous leakage should be offered venous surgery for ED. In congenital venous leakage, the venous insufficiency is typically through abnormal crural veins or the superficial dorsal vein and is amenable to surgical cure. Traumatic venous leak is usually due to localized damage to the tunica albuginea or formation of a fistula between the corpus cavernosum and the corpus spongiosum. Repair of the tunic or closure of the fistula may result in significant improvement of erectile function. In older men with chronic systemic diseases, venous leakage is usually caused by age-related cavernous smooth muscle atrophy, endothelial dysfunction, and degeneration of tunica albuginea with loss of function. In these men, venous ligation surgery is not recommended, and penile prosthesis is preferred.

KEY POINTS

- For all men with ED, it is important to address co-morbid medical and behavioral health conditions and to encourage a healthy lifestyle (diet, nutrition, activity, body weight, stress reduction, and sleep). Mental health plays a critical role in sexual wellness, and a psychological component, either as a consequent development or as principal etiology, is virtually always present in ED patients.
- Young men with ED are at increased risk of CV events, and ED may be the first sign of significant vascular disease.
- ED treatment options include nonmedical/nonsurgical (VED, adaptive sexuality), medical (PED5Is, ICI, MUSE), and surgical options (penile prosthesis). PDE5 inhibitors perpetuate the effect of nitric oxide; they are contraindicated in patients who are on stable nitrate therapy due to the risk of profound hypotension. After thorough counseling, all ED treatment options can be considered first-line therapy, based on patient preference.

  Most clinicians recommend starting with the least invasive treatments and progressing to the more invasive or irrevocable options when other options fail.
- Vascular surgery for ED is very rarely indicated but for very young men with focal arterial occlusion, and venous surgery for ED is not recommended.

ADDITIONAL CONDITIONS CONTRIBUTING TO MALE SEXUAL DYSFUNCTION

Disorders of Ejaculation, Emission, and Orgasm

Distinct physiologic mechanisms are involved in erection, emission, ejaculation, and orgasm (Table 109.7). Emission and ejaculation require stimulation of the external genitalia, except for nocturnal emissions. Signals from the pudendal nerves travel to the upper lumbar spinal sympathetic nuclei. Efferent signals travel in the hypogastric nerve to activate secretions and coordinate the passage of sperm and fluid from the epididymis, vasa deferentia, seminal vesicles, and prostate to the prostatic urethra. The internal urethral sphincter then closes, and the external sphincters relaxes in a synchronized fashion to force the semen into the bulbous urethra, a process called emission. The bulbocavernosus muscles then contract rhythmically and force the semen through the urethra to expel the ejaculate. The external ejaculation process involves the somatomotor efferent of the pudendal nerve to contract the bulbocavernous muscle, but this is involuntary, requiring integrated autonomic and somatic activation.[15] The mechanisms of orgasm, which involves cerebral interpretation of and response to sexual stimuli, is the least understood of sexual processes. Along with emission and ejaculation, several nongenital effects occur, including tachycardia, tachypnea, hypertension, and pulsatile contraction of the anal sphincter.

Retrograde ejaculation (RE) and **failure of emission** present in a similar way, with no visible antegrade ejaculate after orgasm. A thorough medical and surgical history, along with a post-orgasmic urinalysis (POU), will likely differentiate the two conditions. RE is the result of dysfunction of the internal sphincter or the bladder neck, commonly seen with alpha-blocker therapy for benign prostatic hyperplasia, in autonomic neuropathy from diabetes, and after transurethral resection of the prostate. Disruption of the retroperitoneal sympathetic nerves, such as during retroperitoneal lymphadenectomy for testis malignancy or from spinal injury at the level of L2, may result in failure of emission. To differentiate these conditions, a postorgasmic microscopic evaluation of the urine, or POU, should be performed. If there are no sperm in the POU, failure of emission can be diagnosed. If there are sperm in the POU, RE can be diagnosed.

Cessation of alpha-adrenergic blocker therapy may reverse RE in some patients. Alpha-sympathomimetics, such as ephedrine and pseudoephedrine, have been used successfully in patients with RE.[103] For spinal cord injury patients with failure of emission, electroejaculation, via a rectal probe that directly stimulates nerves via electrical impulses, has been applied with some success.[104] For patients who have normal nocturnal emissions but cannot achieve orgasm and ejaculation, psychosexual therapy is recommended.

Delayed orgasm, **DE**, and **decreased penile sensation** may also be complaints encountered during evaluation of sexual dysfunction**.** For these patients, finding an effective and satisfactory treatment can be challenging**.** Complaints of DE may be associated with certain medications, such as selective serotonin reuptake inhibitors (SSRIs) for depression. If this is the case, the patient should be referred to the prescriber for a discussion of the medication and sexual side effects to see if an alternative agent might be equally beneficial. For other men with these conditions, a handheld medical device called Viberect (Reflexonic, LLC, Chambersburg, PA, USA) may be considered as primary therapy. This device provides vibratory stimulation to the penile genital afferent nerves, provoking erection via neurostimulation. In some patients, it may also provoke emission and ejaculation.

PE, or **rapid ejaculation**, a persistent or recurrent occurrence of ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it, is reported by up to 20% to 30% of men.[7] There are multiple recent clinical guidelines from various urological societies that may serve as a clinical reference for evaluation and treatment of PE.[6,34,39] To reduce penile sensitivity, a condom or a topical anesthetizing cream (lidocaine-prilocaine) can be applied to the glans penis. Although time to ejaculation may be prolonged, many men report penile numbness or loss of erection with this treatment. In addition to psychotherapy or behavioral therapy, an SSRI, such as paroxetine (10–40 mg daily or 20 mg 3–4 hours before intercourse) may be used as pharmacotherapy for PE, although this indication is not FDA-approved.[6] A short-acting SSRI, dapoxetine hydrochloride, has been developed for on-demand use in PE but has not yet been approved by FDA, despite several large phase III studies demonstrating efficacy. In the trials, the most common side effects were nausea, dizziness, diarrhea, and headache, and there was no SSRI discontinuation syndrome after abrupt withdrawal.[105]

Peyronie Disease

PD, or plastic induration of the penis, is an acquired, progressive connective tissue disorder of the tunica albuginea of the penis that effects between 3% and 9% of men.[106,107] Some experts suspect that the true prevalence of PD may be even higher. PD occurs most commonly in Caucasian men between the ages of 45 and 60 years, but can occur in men regardless of race or age. The underlying pathogenesis of PD is unknown, but the process is likely related to aberrant would healing, genetic predisposition, repetitive microtrauma to the erect penis during intercourse, and subsequent tissue ischemia.[108] Symptoms of PD include penile pain at rest or with erection, penile curvature or other deformity, and difficulty with erection and penetrative intercourse. Physical examination may reveal palpable penile plaque or dense scar of the tunica. Frequently, PD has significant adverse effects on quality of life, self-esteem, and relationships, resulting in considerable distress in both the patients and their sexual partners.[109] PD is described as a two-phase disease for clinical purposes and to help in staging definitive surgical therapy when indicated and desired. The acute (inflammatory or active) phase is characterized by penile inflammation, penile pain in the flaccid or erect state, growth of penile plaque, and progressive deformity. Pain usually resolves in 90% of patients during the first 6 months.[110] The chronic (fibrotic or stable) phase usually occurs 6 to 12 months later, when the inflammation resolves and the pain, plaque, and penile deformity stabilize. At this stage, improvement in penile curvature and deformity are rare.[111] Studies show that, without treatment, penile deformity worsens in 30% to 50% of patients, stabilizes in 47% to 67% of patients, and improves in 3% to 13% of patients.[111-113]

Determining the appropriate treatment for PD depends on a variety of factors: patient bother, stage of the disease, the presence of pain, severity and direction of the curvature, penile length, and erectile function.[114] There are published guidelines for the treatment of PD,[110,115] but the authors of this chapter diverge from the guidelines regarding treatment strategies for PD. Nonsurgical treatments, including pharmacotherapies, topical treatments, and intralesional injection therapy, endeavor to alleviate pain, halt disease progression, and stabilize deformity.[116] Oral therapy is indicated in men with acute disease and penile deformity associated with bother. We utilize pentoxifylline as first-line oral therapy as a key component of multimodal therapy that also includes intralesional injection[117] and traction[118] at the appropriate time during disease progression. Pentoxifylline is a nonspecific phosphodiesterase inhibitor that inhibits TGF-β1-mediated inflammation, prevents deposition of collagen type 1, and increases NO. Various other options for oral therapy, which are not recommended, have been suggested, including colchicine, PDE5 inhibitors, vitamin E, potaba, tamoxifen, carnitine, coenzyme Q10, and omega 3 fatty acids. Well-designed randomized, placebo-controlled trials have been disappointing and failed to demonstrate much benefit of any of these therapies.[110]

Intralesional therapy involves direct injection of a pharmacological agent into the penile plaque. Three intralesional drugs have shown efficacy in randomized trials: collagenase, verapamil, and interferon alpha-2b. Collagenase clostridium histolyticum is the only FDA-approved intralesional treatment for PD and is the intralesional treatment of choice. However, the treatment course is lengthy, consisting of two separate injections (separated by 1–3 days) every 6 weeks, with up to four cycles per plaque. Manual modeling procedures should begin 48 hours after the second injection of the cycle or sooner, if tolerated.[119] Mild adverse effects include penile pain, ecchymosis, erythema, and edema around the injection site. Major adverse events include penile rupture. Other medical modalities such as iontophoresis, topical therapies, extracorporeal shock wave therapy, and radiation therapy, are not recommended.[106]

When nonsurgical treatment for PD fails, surgical treatment can be considered. When a patient has a deformity that impairs sexual function, stable disease (unchanged deformity for 3–12 months), extensive plaque calcification, and a desire for rapid and reliable results, surgery may be indicated.[106,110,115] The goals of surgery are to correct the deformity, to maintain satisfactory penile length and girth, and to preserve rigidity to allow for restoration of penetrative intercourse.[114] Surgical risks include *de novo* or worsened ED, penile shortening, temporary or permanent penile hypoesthesia, chronic pain, the potential for palpation of permanent suture below the skin, or poor cosmesis of the surgical scar.[120] Recurrent curvature may also develop due to performing surgery prematurely prior to stabilization, reactivation of the condition, or the use of absorbable sutures. Procedures for correction of deformities caused by PD are classified as either penile shortening procedures (penile plication) performed on the convex side of the penis or penile lengthening procedures performed on the concave side of the penis. Lengthening procedures are used to avoid penile shortening and require the use of a graft, which carries a higher risk of ED and penile hypoesthesia. Penile prosthesis should be considered in PD associated with ED refractory to medical treatments.[115]

Priapism

Priapism is defined as a prolonged and persistent penile erection that is unrelated to sexual interest or stimulation and lasts longer than 4 hours.[121] Three types of priapism have been described: ischemic (low-flow), nonischemic (high-flow), and stuttering (recurrent).

Ischemic priapism, considered a urologic emergency, is the most common presentation of priapism and is most often idiopathic. Recognized etiologies include malignancy, medications, spinal cord injury, sickle cell disease, and glucose-6-phosphate deficiency.[122,123] The underlying mechanisms of ischemic priapism are poorly understood, but this condition results when occlusion of the venous outflow of the corpora cavernosa prevents arterial inflow, leading to a cascade of tissue ischemia, endothelial and smooth muscle damage, and eventual fibrosis.[121,124] Prompt treatment is essential to ensure the least amount of long-term disability. Treatment can be initiated with corporal aspiration of blood with injection of a diluted alpha-adrenergic agent, such as phenylephrine (500 mcg delivered every 5 minutes), the preferred agent.[121] Other vasoactive agents, such as oral terbutaline, have been deemed less effective.[125] If this is ineffective, or if the duration has been prolonged (>24–48 hours), a shunt procedure may be performed. Typically, a distal shunt between the corpora and the glans is created using a percutaneous or open technique,[126-128] and tunneling procedures may also be indicated in refractory cases.[127-130]

For patients with ischemia lasting longer than 2 days, early implantation of a penile prosthesis may be an option if there is zero response to injectable phenylephrine. Early prosthesis may result in fewer intraoperative and postoperative complications than implantation delayed for several months, with patients reporting higher satisfaction and less penile shortening with early implantation.[131] Early implantation of a penile prosthesis is not obligatory.

Nonischemic priapism is less common and is almost always the consequence or perineal or penile trauma.[132] This condition is not a medical emergency. After trauma, vascular injury to the cavernosal artery or helicine arteries is exacerbated by cyclical penile erection.[133,134] When a fistula forms between an artery and the sinusoidal spaces of the corpora, unregulated arterial inflow results in persistent, painless penile tumescence. Because venous drainage is preserved, the penile tissue does not become ischemic, and the condition is generally painless.[135]

Treatment progresses from least to most invasive and includes observation with penile compression, medical management with androgen ablation, selective arterial embolization, and surgical intervention as the last resort.[121] Androgen ablation, which reduces sleep-related erection to facilitate closure of the vascular injury, for 1 to 3 months can provide an effective option if there is damage to the cavernous artery.[133,134] If androgen ablation fails, more invasive therapies are then recommended.[136]

Recurrent ischemic, or stuttering, priapism is defined as periodic episodic prolonged erections that may evolve into ischemia priapism. Because this condition affects patients with sickle cell disease more commonly than others, microvascular occlusion secondary to hemolysis with stasis of sickled erythrocytes is thought to be a significant contributing factor.[137] Animal models and clinical studies have revealed a role for improper PDE5 regulation and abnormal NO and cGMP signaling and regulation in the pathogenesis of stuttering priapism.[138-140] Therapeutic options for this condition are limited, and the primary goal of contemporary management of stuttering priapism is to prevent additional episodes to reduce the risk of progression to a major ischemic event.[141]

Androgen ablation therapy is an effective, proven therapy to eliminate the erection-promoting effects of androgens.[142] In men with sickle cell disease, treatment with continuous, low-dose daily PDE5 inhibitors may normalize dysregulated PDE5 levels and decrease the frequency of priapism episodes.[143,144]

KEY POINTS

- Patients may refer to all sexual complaints, including problems with penile sensation, premature/delayed ejaculation, emission, orgasm, or penile deformity, as ED. Recording a good sexual history is essential to defining the actual sexual concerns as each issue has specific treatment options. Peyronie's disease is an acquired, progressive, connective tissue disease of the tunica albuginea that causes penile deformities, such as curvature, hourglass, indent, and shortening. Priapism is defined as a prolonged penile erection that is independent of sexual stimulation. There are two main categories of priapism: ischemic (emergency) and non-ischemic (nonurgent). Ejaculatory disorders and orgasmic disorders may also present as ED.

FUTURE DIRECTIONS FOR THE TREATMENT OF ERECTILE DYSFUNCTION

With the exceptions of lifestyle modifications and revascularization procedures, currently available interventions for ED merely treat the problem, offering symptomatic relief rather than a cure for the underlying disease process. The collective desire to develop a cure has stimulated interest in development of novel therapeutics for ED. Multiple preliminary trials have investigated the restorative potential of promising regenerative therapies, including stem cell therapy (SCT), low-intensity extracorporeal shock wave therapy (LiESWT), and platelet-rich plasma (PRP) injection therapy. The underlying mechanisms and the short- and long-term biological effects of these therapies remain to be fully elucidated. Well-designed, rigorous studies are needed to further define the mechanisms of action, safety profiles, efficacy, and protocols for treatment in humans. At this time, these treatments should be reserved for use only in the context of institutional review board–approved clinical trials until such time as a sufficient body of evidence has demonstrated their efficacy and safety.[3]

New Pharmacotherapeutics

Ongoing basic science research is attempting to identify effective therapeutics that target alternative erectogenic molecular pathways for PDE5 inhibitor–refractory patients. There is a specific need for pharmacotherapeutics that induce smooth muscle relaxation in the absence of NO. ROCK inhibitors and soluble guanylyl cyclase activators are of particular interest for PDE5 inhibitor nonresponders, as they are independent of the NO pathway. The ROCK pathway plays an important role in maintaining the flaccid state of the penis, in that ROCK phosphorylates and inactivates myosin light chain phosphatase, allowing myosin light chain to stay bound to smooth muscle actin.[145] Inhibition of ROCK produces a mechanism for smooth muscle relaxation. Soluble guanylyl cyclase is an enzyme in the NO pathway that can be directly activated to result in smooth muscle relaxation in the absence of NO production. Further research is warranted regarding these and other pathways and to identify additional promising treatments for ED patients.

Stem Cell Therapy

Over the past decades, there has been considerable excitement about the potential use of stem cell (SC)-based therapies in medicine in general and in the field of urology in specific.[146] SCT has been in use in other fields, such as for graft-versus-host-disease to enhance engraftment in patients receiving allogeneic hematopoietic SC transplantation, since the 1990s.[147] In addition, the antiinflammatory, restorative, and immunomodulatory qualities of SCs are currently being exploited clinically to treat hematologic diseases,[148-150] CVD,[151] neurologic diseases such as Parkinson disease[152] and stroke,[153] and autoimmune disease such as multiple sclerosis[153,154] and lupus,[155] as well as refractory wounds,[156] spinal cord injury,[157] and cartilage defects.[158] It makes sense that the field of urology would also be interested in utilization of this type of approach for acute and chronic urologic illnesses.

SCs have been investigated for ED based on the premise that SCs can differentiate into various cell types, including endothelial cells, smooth muscle cells, Schwann cells, and neurons.[159] One hypothesis suggests that SC transplantation into the penis may replenish these cell concentrations in the corporal tissue in order to restore erectile function. An alternative hypothesis is that transplanted SCs may encourage regeneration of the host's own endothelial and smooth muscle cells or may restore proper interactions between these cells via a paracrine effect.[160] The exact mechanisms through which SCs may augment erectile function are poorly understood at this time.

There have been many preclinical studies utilizing SCs in animal models of ED. For animal trials, most authors utilize an animal model that simulates either an acute iatrogenic trauma to the neurovascular bundle or a chronic disease state, such as aging, or hyperlipidemia. In acute ED models, the mechanism of action of SCs is presumed to be by paracrine action.[161-163] In contrast, in chronic ED the theoretical method of SC action is proposed to be both engraftment and cellular differentiation.[164] However, the exact mechanism of action of SCs in the treatment of ED remains uncertain.[165]

There have been a limited number of clinical trials investigating SC therapy for male sexual dysfunction. Small studies have utilized SCs in human patients with no adverse outcomes, but little can be concluded from these studies regarding the potential restorative effects of SCT. Many questions remain unanswered. Future studies should focus on robust, placebo-controlled, double-blind, randomized design in order to assess the true efficacy of SCT for male sexual dysfunction.

Low-Intensity Extracorporeal Shock Wave Therapy

On the horizon for the treatment of ED is LiESWT, modified as low-intensity pulsed ultrasound or low-energy shock wave therapy (LESWT) in different studies. Provoking widespread enthusiasm from urologists and patients alike for novel noninvasive therapies, LiESWT has already been discussed in the first-line therapy section of the European Association of Urology Sexual Dysfunction Guidelines.[166] The FDA has not yet approved LiESWT for mainstream treatment of ED in the United States, as it is important first to establish the mechanisms of action of the treatment in addition to performing rigorous clinical trials with large numbers of patients, using validated and standardized protocols, and ensuring long-term follow-up to ensure the safety and efficacy of treatment.

Many studies have investigated the mechanisms of action of LiESWT for ED, and it is believed that this therapy has the ability to activate SCs *in situ* to produce such downstream effects as endogenous

SC differentiation with subsequent angiogenesis and tissue regeneration. Animal studies reveal that LiESWT stimulates cell proliferation through activation of integrin receptors and the Rho/ROCK/Src/ERK signaling pathway[167] and by promoting multilineage differentiation of mesenchymal SC lines through the ROCK-Cot/Tpl2-MEK-ERK signaling pathway.[168] Additionally, endogenous SC recruitment and Schwann cell activation coincided with angiogenesis, tissue regeneration, and nerve generation in a rat model of pelvic neurovascular injury after LiESWT treatment.[169] The angiogenesis-promoting effect of LiESWT is believed to involve upregulation of vascular endothelial growth factor. Additionally, LESWT has been shown to markedly improve erectile function[170] through downregulation of receptors for advanced glycation end products[171] and through recruitment of endogenous mesenchymal SCs.[172]

There have been many small, short-term clinical trials and subsequent systematic reviews and metaanalyses to evaluate the efficacy of LiESWT for the treatment of ED. Though there is heterogeneity regarding study design, treatment protocol (dosing, frequency, number of shocks, linear versus focuses device), and follow-up interval, the overall conclusions suggest that there is clinical improvement with LiESWT, with no significant adverse events reported.

Proponents of LiESWT suggest that this regenerative treatment modality will be able to potentially mitigate or eliminate the safety and methodological concerns about SC acquisition, preparation, and delivery and also reduce or eliminate the need for expensive and invasive medical and surgical therapies for ED in many patients. As with all regenerative therapies, the underlying mechanisms of therapeutic ultrasound and the biological effects it has on the human body remain to be thoroughly investigated. Additional well-designed, rigorous studies are needed to further define the mechanisms of action, safety profile, efficacy, and optimal treatment protocols for this promising therapy.

Platelet-Rich Plasma

In recent years, PRP injection therapies have been utilized in many fields of medicine in hopes of restoring structure and function to diseased tissues. This therapy is based on the hypothesis that biologically active molecules including growth factors can upregulate downstream cell regeneration. For the PRP procedure, whole blood is withdrawn from the patient and then centrifuged to produce autologous plasma containing four times the normal concentration of platelets and growth factors. This concentrated plasma is then injected into the structure of concern. Beyond promising initial studies, which were limited by a low number of animals and unconventional ICP monitoring techniques, there has been a lack of significant basic science exploring the mechanisms and efficacy of PRP for ED. Additional animal studies are necessary for elucidation of the mechanisms of RPR in erectile recovery.

Across the globe, however, there are already human trials underway to investigate the use and safety of PRP in human subjects. Thus far, there have been no major adverse outcomes, and no patients have reported worsening of their ED. These studies, however, have had low patient numbers, have suffered from the lack of a control group, and have shown uncertain efficacy. Overall, current data suggest that PRP for ED is safe in humans, but no studies have determined whether there is any long-term functional benefit in the context of sexual medicine.[173] Good-quality randomized, prospective, placebo-controlled trials are needed before PRP can be recommended as a therapy for ED.

KEY POINTS

- Multiple regenerative therapies, including stem cell therapy, low intensity extracorporeal shock wave therapy, and platelet rich plasma, are under investigation in hopes of providing either a durable treatment or curative therapy for ED. At the time of this writing, these potentially restorative and regenerative therapies remain under investigation and are not recommended by professional guidelines for the treatment of ED outside of clinical trials.

CONCLUSIONS

Over the past three decades, the treatment algorithm for ED has been transformed by discovery. Whereas psychosexual therapy was once the only therapeutic option, patients can now choose from multiple efficacious pharmacologic agents and progress, if necessary, to highly effective and safe surgical interventions. New and improved therapies for ED will continue to emerge as our understanding of the basic mechanisms of penile erection continues to evolve. Penile erection is a complex physiological phenomenon that is reliant not only on neurovascular components, but also on psychological wellness. A thorough understanding of the mechanisms of penile erection and the medical, surgical, and psychosocial conditions that contribute to ED facilitates the evaluation and management of patients with this distressing condition.

Conclusion, 1857

Anabolic androgenic steroids (AAS) are a group of steroid hormones, including testosterone and its synthetic derivatives, that have been in use for the past eight decades. In addition to their anabolic effects on the skeletal muscles and bone, androgens promote and maintain male secondary sexual characteristics, sexual function, and sexual behavior, and are used in the treatment of male androgen deficiency. However, there is an important distinction between treatment with testosterone at physiologic doses in organic male hypogonadism and abuse of AAS as pharmacotherapy for the purposes of achieving competitive advantage in sports or for “image enhancement” for cosmetic reasons. Indeed, few topics in medicine have generated more interest and controversy, both among the clinicians and lay public, than abuse of AAS for nonmedical reasons. This controversy is further compounded by the fact that the long-term safety of these steroids remains unclear. Additionally, there are no effective strategies to treat men who have discontinued or plan to discontinue AAS and are either experiencing or are concerned about AAS-withdrawal syndrome. The paucity of high-quality data in these areas foments the disregard toward medical advice related to adverse effects associated with AAS abuse,[1,2] with users often assuming that the physicians are misinformed regarding the consequences of AAS abuse.[3]

This chapter focuses on the pharmacological use of AAS in men, including (1) the history and epidemiology of AAS abuse, (2) types of doping, (3) methods used in the detection of AAS, (4) adverse health consequences of AAS abuse, and (5) management options in men who are rendered hypogonadal as a result of prior AAS abuse.

AAS: USE, MISUSE, AND ABUSE

At the beginning of this chapter, we highlight various terms associated with the use of AAS.

Use

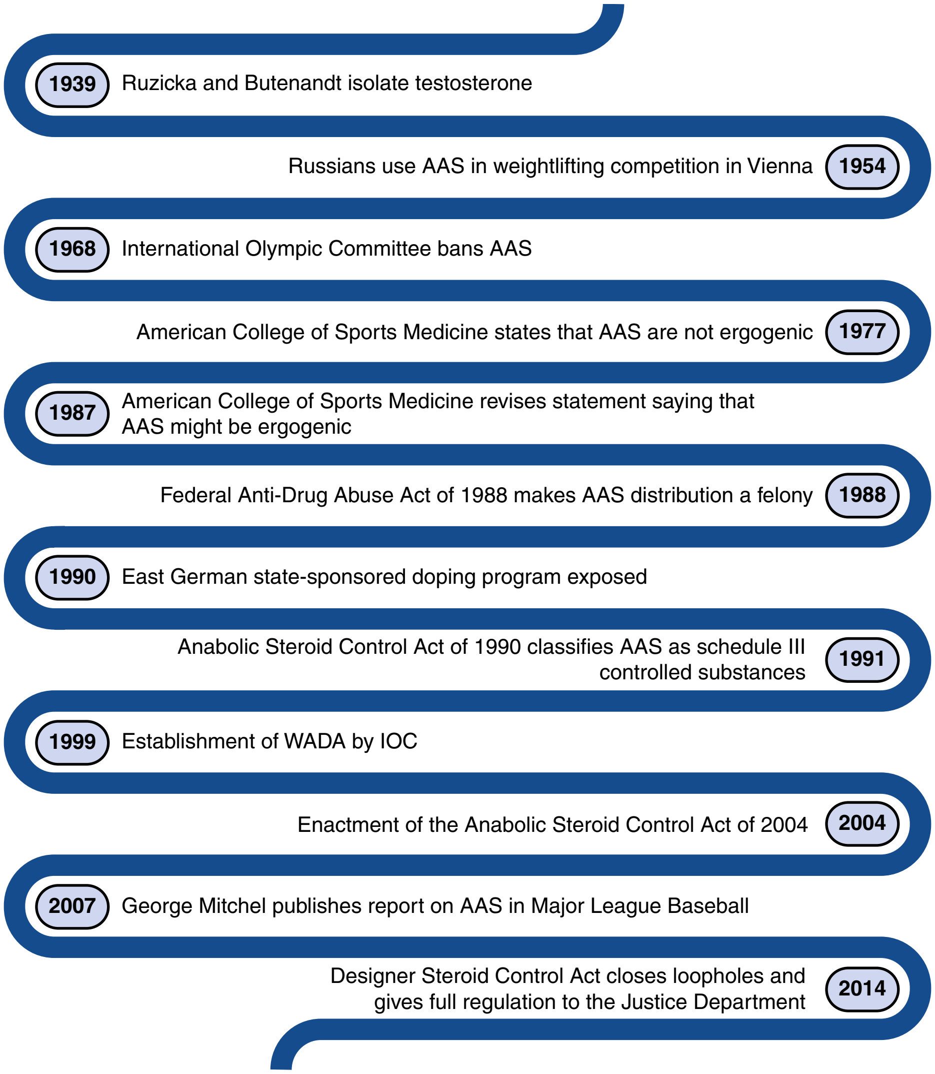
The *use* of AAS implies taking prescription androgens (mainly testosterone) for medical conditions. An example is the treatment of hypogonadal men with organic diseases of the hypothalamus, pituitary, or testes. Testosterone therapy, at physiologic dose, is indicated to induce or maintain secondary sexual characteristics.

Misuse

The *misuse* constitutes systematic prescribing of AAS for unproven medical indications in men who do not have organic androgen deficiency. This includes prescribing androgens to treat obesity, diabetes, impaired cognition, or reverse aging.

Abuse

The *abuse* of AAS constitutes their use for nonmedical purposes where they are often used in supraphysiologic doses for either the purposes of performance enhancement (competitive sports) or image



1939 Ruzicka and Butenandt isolate testosterone
1954 Russians use AAS in weightlifting competition in Vienna
1968 International Olympic Committee bans AAS
1977 American College of Sports Medicine states that AAS are not ergogenic
1987 American College of Sports Medicine revises statement saying that AAS might be ergogenic
1988 Federal Anti-Drug Abuse Act of 1988 makes AAS distribution a felony
1990 East German state-sponsored doping program exposed
1991 Anabolic Steroid Control Act of 1990 classifies AAS as schedule III controlled substances
1999 Establishment of WADA by IOC
2004 Enactment of the Anabolic Steroid Control Act of 2004
2007 George Mitchel publishes report on AAS in Major League Baseball
2014 Designer Steroid Control Act closes loopholes and gives full regulation to the Justice Department

Figure 110.1 Timeline of important events in the discovery and abuse of anabolic androgenic steroids (AAS). *IOC,* International Olympic Committee; *WADA,* World Anti-Doping Agency.

enhancement. In these situations, AAS are usually procured illicitly from compounding pharmacies, fitness centers, or veterinary clinics. This chapter will focus on this patient population.

HISTORY AND EPIDEMIOLOGY OF ANABOLIC STEROID ABUSE

History of Anabolic Steroid Abuse

The culture of using ergogenic (performance-enhancing) compounds among athletes dates to ancient Greece, where herbal remedies and animal extracts were used by athletes to gain competitive edge. Thus, the history of “doping” began long before the discovery of testosterone by Butenandt in the 1930s. However, the attribution of athletic prowess to testicular secretion dates back to the 18th century when experiments by John Hunter showed that testicular transplantation in any anatomical location maintained cock combs.[4] In the 1870s, Charles Edouard Brown-Séquard, a 72-year-old physician-scientist, hypothesized that injections of testicular extracts from young animals possessed rejuvenating effects and decided to use himself as the first human subject. He self-administered 10 doses of this extract subcutaneously over 2 weeks and reported improvement in strength and endurance.[5] The news of Brown-Séquard’s “Elixir of Life” quickly spread throughout Europe and North America, where it was commercially sold for decades. However, replication of Brown-Séquard’s published methods demonstrated that his elixir had insufficient concentrations of testosterone to produce a biological response[6]; thus, the birth of Andrology began with demonstration of the *placebo effect*. Six decades later, Butenandt and Ruzicka won the Nobel Prize for the synthesis of testosterone. Subsequently, chemists and compounding pharmacies made numerous derivatives of testosterone in the 1950s. Although powerlifters were the first group of athletes to abuse AAS for competitions (Fig. 110.1),[7] AAS abuse soon spread to other athletes, including those participating in the Olympic Games.[8] The most well-known phase of AAS abuse in the history of Olympics was the systematic administration of AAS to the Soviet weightlifting team in the 1952 and 1956 Olympic Games.[8] In the United States, the credit for introducing AAS to American athletes goes to Dr. John Ziegler, a physician member of the US Weightlifting Team, who learned about the use of AAS by the Russian team during his trip to weightlifting championships in Vienna in 1954.[9] Upon return, he administered testosterone to weightlifters in the York Babel Club in Pennsylvania. In the 1960s, the German Democratic Republic instituted a program of systematic doping of their Olympic athletes with AAS, which led to winning 153 Olympic gold medals from 1968 to 1988, despite having a population of only 18 million.[7]

While athletes were well aware of the ergogenic effects of AAS, the scientific community and the general public remained skeptical. Although the International Olympic Committee (IOC) prohibited the use of AAS in 1974, a position paper from the American College of Sports Medicine in 1977 still raised doubts regarding the ergogenic potential of AAS.[10] It was not until 1996 that the effects of AAS on strength were demonstrated in a well-controlled study.[11] Currently, the scrutiny of doping in sports is conducted by the World Anti-Doping Agency (WADA), a subsidiary of IOC. Every year WADA publishes an ever-growing list of prohibited drugs; however, androgens remain the most commonly used ergogenic drugs in sports.[7]

Epidemiology of Anabolic Steroid Abuse

The epidemiology of AAS abuse in athletes and in the general public has been difficult to ascertain.[12,13] Questionnaire-based studies of elite college athletes in the United States have demonstrated a lifetime prevalence of 20%. In one frequently cited study, Goldman et al. presented a Faustian bargain to world-class athletes biannually between 1982 and 1995, asking if they would agree to take a drug that would guarantee an Olympic gold medal without being caught, but which would also result in their death within 5 years (The Goldman Dilemma).[14] Interestingly, 52% of the athletes said they would accept the "death-for-gold" deal. In 2013, another study revisited the Goldman Dilemma in 212 elite track athletes and found that 12% would still take a hypothetical illegal performance-enhancing drug if it was undetectable and guaranteed an Olympic gold medal, but only 2% would accept the *death-for-gold* deal.[15]

In the general American public, questionnaire-based studies have suggested lifetime prevalence of up to 15%,[13] with 98% of users being men.[16] It is estimated that 3 to 4 million males between age 13 and 50 years in the United States have used AAS. The lifetime prevalence of AAS use is higher among gay and bisexual men (21%) as well as among ethnic minorities (25%).[17] Over the decades, the abuse of AAS has permeated beyond competitive sports, as elite athletes account for only a small fraction of AAS users in the United States.[16] Most of the users are noncompetitive weightlifters and men who are keen to acquire muscular appearance for image-enhancing purposes. The desire to become muscular among some men is influenced by exposure to muscular male images in mass media while others may have muscle dysmorphia, a body image disorder that manifests as an obsessive preoccupation with a muscular appearance. It is estimated that approximately 45% of men with muscle dysmorphia may have used AAS.[18]

Worldwide, the lifetime prevalence of AAS abuse among men is estimated to be 1% to 5%. Although most Western cultures currently have an endemic problem with AAS abuse, East Asian cultures, such as Chinese and Japanese cultures, appear to be largely shielded from this public health issue; this is likely due to the fact that Confucian tradition associates masculinity with intellect and integrity rather than physical strength.[19] In contrast, in the Nordic culture, where physical strength has been valued since the origins of Norse mythology, the lifetime prevalence of AAS abuse is high at 2.4% in Norwegians and 4.4% among the Swedes.[20]

KEY POINTS

- AAS abuse, initially limited to elite athletes, has now permeated the general population where it is mainly used for the purposes of image enhancement.
- The lifetime prevalence of AAS abuse in the general population is estimated to be 5%, 98% of these being men.

ERGOGENIC POTENTIAL OF ANABOLIC STEROIDS

While elite and amateur athletes had been aware of the anabolic effects of AAS on skeletal muscles for decades, the scientific community continued to attribute ergogenic effects of AAS solely to their influence on motivation, arguing that only men who trained harder and longer while taking AAS experienced improved performance. This skepticism started to abate in 1987 when the American College of Sports Medicine revised its original conclusion that AAS did not increase muscle strength.[21] However, it was only in 1996 that the medical community fully accepted the anabolic effects of AAS after a well-controlled study conclusively demonstrated that administration of supraphysiologic doses of testosterone (600 mg/week) increased muscle strength in young healthy men; this study also showed that the effects of testosterone and exercise were additive.[11] Men who only received testosterone experienced an increase in fat-free mass of 3.2 kg compared to the placebo plus exercise group who had an increase of 1.9 kg. On the other hand, the increase in fat-free mass in the testosterone plus exercise group was 6.1 kg.[11] The synergistic effects of testosterone and resistance training on muscle strength have since been verified in other studies.[22] Similarly, studies have shown that suppression of endogenous testosterone in men reduces muscle mass and strength.[23]

The anabolic actions of AAS on skeletal muscle involve several mechanisms that include: (1) muscle fiber hyperplasia and hypertrophy, (2) differentiation of mesenchymal pluripotent stem cells toward myogenic rather than adipogenic lineage,[24] (3) stimulation of skeletal muscle protein synthesis,[25,26] and (4) reduction of muscle catabolism via inhibition of the ubiquitin proteasome and myostatin pathways.[25,27] Testosterone administration also leads to the activation of muscle satellite cells.[28,29]

In addition to their direct effects via androgen receptor (AR), AAS also exert their anabolic effects via stimulation of growth hormone (GH) secretion. Indeed, testosterone replacement in hypogonadal men has been shown to increase serum concentrations of GH[30] and an increase in intramuscular insulin-like growth factor-1 (IGF-1) mRNA expression. Additionally, AAS may also improve physical performance via stimulation of erythropoiesis, which results in an increase in oxygen-carrying capacity and endurance.

KEY POINTS

- The ergogenic effects of AAS are due to their direct anabolic action on skeletal muscles where they stimulate muscle fiber hyperplasia and hypertrophy, promote differentiation of mesenchymal pluripotent stem cells toward myogenic lineage, and increase protein incorporation.
- The end result is an increase in muscle mass and strength. Additionally, stimulation of erythropoiesis by androgens increases endurance.

TYPES AND PATTERNS OF ANDROGEN DOPING

Men who abuse AAS rely on two main doping strategies (Table 110.1).

Indirect Doping: This involves use of drugs that increase endogenous testosterone production.

Direct Doping: This includes direct use of both natural and synthetic steroids (including testosterone).

In addition to traditional AAS, there has been a remarkable proliferation of new nonsteroidal anabolic agents that are increasingly being used in conjunction with traditional AAS, such as selective androgen receptor modulators (SARMs).[31–33] The practice of abusing multiple anabolic agents simultaneously is known as "stacking," which involves

TABLE 110.1 Drugs Used in Direct and Indirect Doping

Direct Doping

Naturally Occurring Anabolic Steroids
Testosterone
Epitestosterone
Dihydrotestosterone
Nandrolone
Boldenone

Synthetic Anabolic Steroids
Clostebol
Danazol
Drostanolone
Ethylestrenol
Fluoxymesterone
Gestrinone
Methandienone
Methenolone
Methyltestosterone
Norethandrolone
Oxandrolone
Oxymetholone
Stanozolol
Tibolone
Trenbolone

Designer Steroids
Boldione (precursor to boldenone)
Dimethazine
Mentabolan
Methasteron
Methoxygonadiene
Methylclostebol
Methylepistiostanol
Methylstenbone
Methylstenbolone
Prostanozolol (precursor to stanozolol)

Selective Androgen Receptor Modulators
GTx-024
LGD-4033
RAD140
S-4
S-23
YK11

Indirect Doping

Testosterone Precursors
DHEA
Androstenedione

Selective Estrogen Receptor Modulators
Clomiphene
Droloxifene
Raloxifene
Tamoxifen
Toremifene

Gonadotropins
Human chorionic gonadotropin
Recombinant human LH

Aromatase inhibitors
Anastrozole
Letrozole
Vorozole
Atamestane
Exemestane
Testolactone

Selective Estrogen Receptor Degraders
Fulvestrant

mixing a variety of oral and injectable drugs that are considered to have synergistic effects on muscle mass and strength. Some men follow the practice of "cycling," with planned periods of AAS use ("on") followed by abstinence ("off"). It is believed that the "off" period prevents desensitization of AR (an unproven concept). Some users apply the "blast and cruise" technique, in which continuous "blasts" of high-dose AAS use is interspaced with lower-dose "cruise."

Direct Doping

This type of doping involves the direct use of testosterone and its steroid derivatives. Additionally, other compounds, such as SARMs (designed to have selective effects on some but not all tissues), are also increasingly being used. The following are the classes of drugs used in direct doping.

Naturally Occurring AAS. The naturally occurring steroids commonly used in direct doping include testosterone, nandrolone, and boldenone. Testosterone esters are by far the most commonly abused AAS.[34–36] The physiological dose of testosterone replacement in hypogonadal men is 100 mg every week intramuscularly; men who abuse testosterone may take as much as 6000 mg weekly. Testosterone is aromatized to estradiol by the aromatase enzyme complex via two successive hydroxylations on the C19 methyl group of testosterone; *Nandrolone* (19-nortestosterone) is a penultimate step in the aromatization process,[37] thus making it a naturally occurring AAS. Exogenous nandrolone is poorly aromatized, but it upregulates aromatase expression.[38] Therefore, men "stacking" nandrolone with testosterone are more likely to develop gynecomastia. Nandrolone is also 5α-reduced, a process that increases its androgenic effects. Nandrolone was previously used medically in the treatment of anemia of chronic kidney disease[39] but is no longer manufactured in the United States. However, it still remains a popular AAS, both for the purposes of performance and image enhancement.[34,36] *Boldenone*, also known as equipoise, is a naturally occurring androgen in animals that can rarely be detected in urine samples of nondoping athletes.[40] Boldenone is currently marketed for veterinary purposes and is among the most abused AAS.

Synthetic Androgenic Steroids. Shortly after the isolation and synthesis of testosterone, several synthetic AAS were developed for clinical use (Table 110.1). Among the most commonly abused synthetic AAS are stanozolol, oxandrolone, trenbolone, and methandienone.[34,36] Some of these steroids are still used for select medical conditions. For example, oxandrolone is often used as an anabolic agent in patients with severe burn injuries to counter catabolism[41] and in patients with Turner syndrome receiving GH therapy. However, the remaining synthetic AAS developed are no longer used for medical purposes.

Designer Steroids. A "designer steroid" is an AAS that is synthesized from a known parent compound and is chemically modified with the intent to circumvent substance control laws.[42] These agents were initially sold legally as supplements until 2015 but were labeled as controlled substances after passing of the Designer Anabolic Steroid Control Act of 2014.[43] The modifications in these compounds are also thought to alter the anabolic and androgenic effects of these steroids. Norbolethone has been credited as the first designer androgen that was originally discovered in the 1960s and its chemical signature was identified in 2002.[44] A year later, tetrahydrogestrinone, a derivative of gestrinone (a progestin), was identified.[45] In 2005, a third designer androgen, desoxymethyltestosterone, was identified. These compounds are banned by the World Anti-Doping Agency (WADA), though their ergogenic potential remains unclear.

SARMs. For decades, scientists have been on a quest to dissect out the anabolic properties of androgens from their androgenic potential. With the discovery of SARMs, this endeavor came to fruition, as these compounds achieved tissue selectivity by exerting anabolic effects on the skeletal muscle and bone while sparing the prostate. This tissue selectivity is considered important in the elderly, who are at a higher risk of prostate abnormalities.[46] The first SARM was synthesized in 1998 and derived from AR antagonists, flutamide and bicalutamide. Over the years, four groups of SARMs have been synthesized: (1) arylpropionamides, (2) bicyclic hydantoins, (3) quinolines, and (4) tetrahydroquinolines.

Indirect Doping

Indirect doping denotes use of drugs that increase endogenous testosterone secretion. This can be achieved with compounds that (1) stimulate the hypothalamic-pituitary-gonadal (HPG) axis such as estrogen receptor (ER) antagonists and aromatase inhibitors; (2) directly stimulate the testes, including luteinizing hormone (LH) and its analogs like human chorionic gonadotropin (hCG); and (3) testosterone precursors such as dehydroepiandrosterone (DHEA) and androstenedione (Table 110.1).

Estrogen Blockers. The rationale for using ER antagonists and aromatase inhibitors stems from the fact that estradiol is a more potent negative regulator of the HPG axis than testosterone.[47] This is evident in men with congenital aromatase deficiency in whom serum concentrations of estradiol are undetectable but both serum testosterone and gonadotropins are elevated; estrogen administration suppresses the HPG axis in these patients.[48] Aromatase is a product of the *CYP19* gene and converts testosterone to estradiol. Aromatase inhibitors inhibit aromatase activity, thereby decreasing estradiol synthesis; as a result, serum testosterone concentrations increase by ~50% to 65%,[49] which can still induce myotrophic effects. Among steroidal aromatase inhibitors, aminoglutethimide was the first drug discovered in this class, followed by testolactone, atamestane, and exemestane. Nonsteroidal aromatase inhibitors include anastrozole, letrozole, and vorozole. The ER antagonists increase gonadotropins by blocking the negative feedback of estradiol on the hypothalamus and the pituitary, which in turn increases serum testosterone concentrations. The original antiestrogens were nonsteroidal drugs such as clomiphene and tamoxifen that bind to both ERα and ERβ. Newer nonsteroidal agents have since become available such as raloxifene, toremifene, and droloxifene. In a trial of clomiphene administered for 30 days to healthy eugonadal young men, there was a progressive increase in serum testosterone concentrations by ~146% by day 30, well into the supraphysiological range.[50] Notably, testosterone concentrations were still increasing at the end of the planned intervention period of 30 days.[50] Thus, it remains unclear if a longer treatment duration could result in even higher testosterone levels. Both ER antagonists and aromatase inhibitors are on the WADA's list of banned drugs.

Men who abuse aromatizable AAS commonly "stack" ER antagonists or aromatase inhibitors to avoid development of gynecomastia.[34,35,51] Some men use these drugs after completing a cycle of AAS in an attempt to "hasten" the recovery of the HPG axis, known as "post-cycle therapy."[35]

Gonadotropins. Another form of indirect doping is the use of gonadotropins, such as recombinant LH or hCG, to stimulate the testes directly, bypassing the hypothalamus and the pituitary. Both drugs are currently on the WADA's list of prohibited drugs for male athletes. hCG is a dimeric glycoprotein containing an α and a β subunit that is normally produced by the human placenta[52]; its α-subunit is similar to other glycoprotein hormones, namely, follicle-stimulating hormone (FSH), LH, and thyroid-stimulating hormone (TSH). It undergoes glycosylation with sialic acid residues that prolongs its half-life and makes it a long-acting analog of LH. Clinically, recombinant LH or hCG are used to stimulate spermatogenesis in men who have central hypogonadism and desire fertility.[53] These therapies are expensive and require injections several times per week, but the evidence regarding their ergogenic potential is sparse. Small trials in older men have shown that hCG therapy increases serum testosterone levels and lean body mass but does not improve muscle strength.[54] Men abusing AAS also use hCG to prevent testicular atrophy.

Androgen Precursors. This class of agents include drugs like androstenedione and DHEA. Androstenedione is a prohormone that is produced in both the gonads and the adrenals in both sexes. It is synthesized from DHEA and is converted to testosterone by 17β-hydroxysteroid dehydrogenase. On the other hand, DHEA is predominantly secreted by the adrenal glands. Although the IOC had banned these compounds in the late 1990s, they were sold in an uncontrolled fashion as dietary supplements for the subsequent two decades under the Dietary Supplement Health and Education Act until 2004, when the US Congress added androstenedione to the list of banned drugs.[55] Data suggest that androstenedione at a dose of 300 mg increases serum testosterone by 30%,[56] whereas a dose of 1500 mg improves lean body mass and muscle strength. Similarly, DHEA at high doses (100 mg) improves muscle strength.[57] Although banning of these prohormones by the IOC is justified because of their ergogenic potential, there is still no conclusive evidence that testosterone precursors significantly impact the performance of young athletes.

KEY POINTS

- Direct doping involves the use of testosterone, its synthetic derivatives, and designer androgens (such as SARMs).
- Indirect doping involves the use of drugs that increase endogenous testosterone secretion by stimulating the HPG axis (ER antagonists and aromatase inhibitors) or via direct stimulation of the testes (LH and hCG).

DETECTION OF ANDROGEN DOPING

Detection of Compounds Used in Direct Androgen Doping

Although some athletes use both natural and synthetic AAS to circumvent the detection of synthetic androgens, athletes have resorted to doping mainly with *testosterone*. Hence, the detection of illegal use depends upon distinguishing between endogenous and exogenous testosterone. Detection of exogenous testosterone abuse can be accomplished by two methods: measurement of testosterone-to-epitestosterone (T/E) ratio and isotope ratio mass spectrometry (IRMS), the latter is only performed by specialized laboratories working with antidoping agencies to test elite athletes (not available to clinicians).

Testosterone-to-Epitestosterone Ratio. Epitestosterone (17α-hydroxy-4-androsten-3-one), a 17-epimer of testosterone, is also secreted by the Leydig cells. Epitestosterone is biologically inactive, and there is no interconversion between testosterone and epitestosterone. It is mainly excreted in the urine as a glucuronide.[58] Its production rate is <5% of testosterone, but its urinary excretion is 33% that of testosterone.[59] Because of this rapid clearance, excretion rates of testosterone and epitestosterone are similar, resulting in urinary T/E ratio of ~1. Because there is no interconversion between the two compounds, administration of exogenous testosterone results in an increase in the T/E ratio. Assessment of T/E ratio in a large number of athletes has shown that generally the ratio remains below 6.[60] This initially led the IOC to adopt the cutoff threshold of 6 to consider a test as "positive." However, it was later recognized that genetic differences in various populations influences T/E ratio as some athletes have lower rates of endogenous epitestosterone production; thus, their T/E ratio naturally exceeds 6. On the other side of the spectrum, a deletion polymorphism in uridine diphosphate glucuronyl transferase 2B17, an enzyme that facilitates epitestosterone excretion, lowers T/E ratios.[61] Considering these genetic variants, the IOC recently lowered the T/E cutoff ratio to 4. Hence, any value above 4 is considered as "suspicious." To complicate

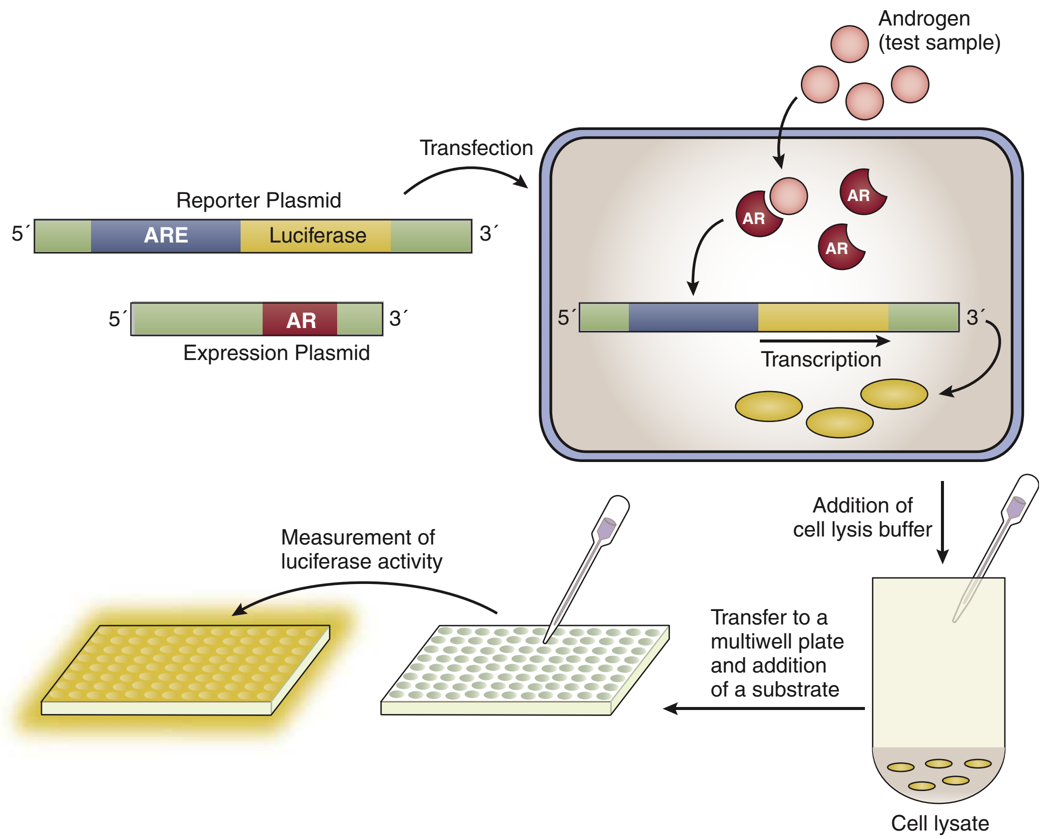


Figure 110.2 Detection of designer androgens by the luciferase reporter gene bioassay. *AR,* androgen receptor; *ARE,* androgen response element.

matters, some athletes may mask the use of exogenous testosterone by coadministration of epitestosterone.[62] In such cases, the exogenous use of epitestosterone can be detected by elevated concentrations of its urinary metabolites. Generally, the T/E ratio remains largely unchanged in athletes not using AAS. Therefore, serial T/E ratio measurement in the same individual is an important tool that aids in the detection of exogenous administration of testosterone.

Isotope Ratio Mass Spectrometry (IRMS). If the T/E ratio is abnormal among elite athletes, the WADA requires additional confirmation by gas chromatography-combustion-IRMS, which involves measurement of $^{13}C/^{12}C$ isotope ratio in testosterone. This method is based on the premise that the percentage of ^{13}C (a naturally occurring isotope of carbon) in endogenous testosterone (synthesized from carbon sources derived from animals and plants) is higher than in synthetic testosterone (synthetic testosterone has a lower $^{13}C/^{12}C$ ratio). The IRMS involves separation of steroids by gas chromatography and oxidized to carbon dioxide in a combustion chamber. The ratio of $^{13}CO_2/^{12}CO_2$ is measured in a spectrometer.[63] A lower $^{13}C/^{12}C$ ratio suggests exogenous testosterone use. This technology can also distinguish endogenous nandrolone, dihydrotestosterone (DHT), and DHEA from exogenous sources.

Synthetic Androgen Bioassays. Bioassays are increasingly being used in the detection of AAS. Bioassays are functional assays that are used to determine the bioactivity (and potency) of a compound, with the unit of bioactivity defined as the lowest concentration that generates a functional response. This unit is then compared with the known bioactivity of a standard compound (testosterone or DHT). The main utility of these bioassays is to detect novel designer androgens, compounds whose chemical structure is unknown (radioimmunoassay and mass spectrometry only detect AAS whose chemical signature is known). These bioassays are available in laboratories associated with doping agencies that monitor elite athletes and are not available to clinicians. Bioassays can be divided into *in vivo* and *in vitro* assays. The *in vivo* assays assess the response of androgenic stimulation on androgen-dependent tissues such as capon comb, skeletal muscles, or seminal vesicles. As these assays are time consuming, the *in vitro* assays are used more commonly as they are faster, relatively inexpensive, and have high throughput. There are three types of *in vitro* assays:

1. **Receptor Binding Assays:** These assays evaluate the ability of an androgen (test sample) to bind to the AR in the presence of a known radioactive ligand for the receptor. The displacement of the ligand from the AR by the test sample correlates with its bioavailability.
2. **Cell Proliferation Assays:** These assays assess the bioactivity of an unknown AAS by its ability to stimulate proliferation of androgen-dependent cell lines, e.g., human prostate cancer cells. These assays are sensitive but not specific for androgens.
3. **Reporter Gene Assays:** In these assays, the bioactivity of AAS is measured by the degree of expression of the reporter gene (Fig. 110.2).[64] These assays are performed in yeast or mammalian cells. The process involves selecting a host cell line that does not express an endogenous AR. The next step involves introduction of two plasmids into the cell line: (1) an expression plasmid for constitutive expression of AR in the cells and (2) a reporter plasmid in which the androgen response element sequences drive the expression of firefly luciferase that serves as the reporter gene.[64] The amount of luciferase expression is proportional to the bioactivity of the AAS being tested and is measured by luminometry. These bioassays have been optimized for high-throughput screening and can detect a variety

of designer steroids but are mainly available in specialized laboratories working with antidoping agencies.

Ketoconazole. Ketoconazole, an antifungal agent, is an inhibitor of endogenous steroid synthesis, including testosterone and epitestosterone.[75] Because there is no interconversion between testosterone and epitestosterone and because epitestosterone is more readily excreted in urine than testosterone, ketoconazole increases T/E ratio in men using exogenous testosterone (as it inhibits testicular epitestosterone secretion). In contrast, in men with naturally occurring high urinary T/E ratios, ketoconazole does not affect the T/E ratio as it inhibits secretion of both testosterone and epitestosterone.[76] This forms the basis for the ketoconazole test, which is used to differentiate exogenous from endogenous testosterone in men who present with an elevated T/E ratio.

Detection of Compounds Used in Indirect Androgen Doping

High-performance immunoassays are used to detect LH in men suspected of using it for indirect doping. The detection of hCG is initially performed with immunoassays, and if positive, confirmation is carried out with immune extraction and mass spectrometry.[65] As hCG does not alter T/E ratio, this methodology is not useful in the detection of indirect doping with hCG. Detection of doping with aromatase inhibitors and ER antagonists is performed by liquid or gas chromatography mass spectrometry (GC-MS).[66,67] Use of DHEA and androstenedione result in an increase in T/E ratio,[68,69] which is then confirmed by measurement of $^{13}C/^{12}C$ ratio with IRMS. Confirmation of doping with androstenedione can also be accomplished by measurement of its metabolite, 4-hydroxyandrostenedione, by either mass spectrometry or IRMS.[70] Use of high doses of testosterone precursors also alters the ratios of metabolites of endogenous androgens. For example, administration of DHEA increases urinary androsterone and results in a high androsterone/testosterone ratio.[68]

KEY POINTS

- Detection of doping with exogenous testosterone can be accomplished by measuring the testosterone-to-epitestosterone (T/E) ratio or via IRMS.
- Bioassays can aid in the detection of AAS whose molecular structure is not known.
- Indirect doping with LH or hCG can be detected by immunoassays.

Evaluation Process of AAS Abuse in Elite Athletes

In this section, we elaborate on the procedures that involve the collection and transportation of urine samples for doping tests in elite athletes. The WADA requires all urine samples to be collected under direct visual oversight of an accredited supervisor. After collection, each sample is divided into two parts (samples A and B) before transporting them to a WADA-accredited laboratory. Confirmatory testing consists of remeasurement of any suspicious analytes in an additional aliquot of the athlete's original "A" sample; the "B" sample is used as necessary for additional confirmatory testing if the "A" sample tests positive for a suspicious substance. If the second sample is also positive, then doping is confirmed. This information is then conveyed to the appropriate sports organization. In 2006, approximately 50% of the positive doping results were due to androgens, which were three times higher than the next category of banned drugs. As a result, WADA conducts screening for AAS using mass spectrometry to detect even trace quantities of natural or synthetic androgens.

An important tool in the detection of AAS abuse (and other performance-enhancing drugs) has been the "biological passport." The concept of a biological passport assumes that an individual's serum and urine hormone and prohormone concentrations do not change significantly over time.[71] An athlete's urine and serum testosterone, DHT, epitestosterone, and their precursors are measured before the first competition and are followed longitudinally. Additional testing follows any deviation from baseline that is considered significant. The biological passport is intended to detect attempts by athletes to use exogenous AAS or attempts to increase endogenous AAS by drugs that stimulate the HPG axis and increase endogenous production of AAS. The shortcomings of this process is that it assumes that the athletes have not used AAS prior to the first collection of samples at the time of enrollment. Therefore, this initial collection of samples may not reflect the "true" baseline status in such athletes.[72] The laboratory will also assess for the presence of compounds that athletes might have used to mask measurement of AAS. Based on the initial result, the laboratory might perform gas chromatography-combustion-IRMS. The final steps of the process of determination of whether an athlete has used an AAS involves expert interpretation of the laboratory results and comparison to previous results in the athlete's biological passport. Determination of an AAS use violation requires a unanimous conclusion of "doping likely" by three independent experts.

Assessment of Men Abusing AAS in the Clinics

Unlike the laboratory services available to antidoping agencies, clinicians do not have access to these tools. Thus, they must rely on their clinical impression and limited assays provided by the commercial laboratories. Abuse of AAS should be considered when a muscular man presents either with low testosterone, infertility, or gynecomastia. Many men who abuse testosterone will give themselves a "drug holiday" from AAS and present to the clinic to seek testosterone treatment for hypogonadal symptoms at the time when their endogenous testosterone is still suppressed (men abusing SARMs or AAS other than testosterone will present with this biochemical profile while still taking these drugs). This incongruence between their muscular phenotype and suppressed serum testosterone levels is often the first indication of AAS abuse. If AAS abuse is suspected, the clinician should directly ask the patient about AAS abuse in a nonjudgmental manner. Clinicians should consider measurement of serum testosterone, FSH, and LH concentrations. As exogenous testosterone, nontestosterone AAS and hCG suppress circulating gonadotropins (Table 110.2), measurement of these hormones is useful in determining the likelihood of AAS abuse. Additionally, elevated hematocrit, low serum high-density lipoprotein (HDL) cholesterol and sex hormone–binding globulin (SHBG) concentrations also offer a clue to AAS abuse.

STRATEGIES USED BY ATHLETES TO AVOID DETECTION OF ANDROGEN ABUSE

Athletes use several methods to avoid detection of AAS, from urine replacement or adulteration to administration of masking agents. The following includes specific examples of strategies that are used to avoid detection:

Administration of Epitestosterone

The urinary T/E ratio is used to detect doping with exogenous testosterone and the test is considered positive when the T/E ratio is >4. Athletes doping with testosterone may concurrently administer epitestosterone, which decreases T/E ratio and results in a false-negative result.[62] As urinary excretion of epitestosterone is about one-third that of testosterone, coadministration of testosterone and epitestosterone in 30:1 ratio will generally result in a normal T/E ratio.[73] Deviations in the T/E ratio from an athlete's biological passport trigger further investigation but in itself do not constitute a doping violation. These urine samples can be submitted for IRMS confirmation.

Masking Agents

The WADA's list of prohibited substances also includes drugs that are used to mask detection of prohibited agents. Masking agents belong to different classes of medications and have different mechanisms of action. In this section, we will discuss such agents and how they mask detection of AAS.

Probenecid. Probenecid is a uricosuric agent that is used in the treatment of gout. Probenecid is known to interfere with renal excretion of steroid glucuronide conjugates and has been shown to reduce urinary excretion of endogenous (testosterone, epitestosterone, androsterone) and exogenous (norandrosterone, noretiocholanolone) steroid conjugates.[73] Probenecid is detected by GC-MS, and its identification alone is considered sufficient evidence to establish a doping violation.

Steroid 5α-Reductase Inhibitors. These drugs inhibit 5α-reductase, the enzyme that inhibits conversion of testosterone to DHT, and are used in the treatment of benign prostatic hyperplasia and male-pattern baldness. Endogenously produced 5α-reduced steroids (DHT and androsterone) are part of the biological passport in athletes. Concomitant use of finasteride with testosterone alters the urinary steroid profile by reducing the excretion of 5α-reduced steroids without changing the excretion of corresponding 5β-reduced steroids, resulting in a decreased ratio between epimeric 5α- and 5β-reduced steroids. If a 5α-reduced metabolite is targeted for testing, the use of finasteride can mask its detection. Similarly, finasteride inhibits the formation of 19-norandrosterone in nandrolone abuse. Finasteride can be measured by GC-MS and high-performance liquid chromatography (HPLC).

Diuretics. There are several classes of diuretics used in clinical practice to treat hypertension and hypervolemic states. Athletes use diuretics to achieve rapid weight loss in sports with weight restrictions such as boxing and wrestling. Diuretics are also effective masking agents as they increase urine volume and dilute urinary concentrations of AAS and their metabolites to either below the limits of detection or below allowed limits.[74]

KEY POINTS

- Athletes use several methods to avoid detection of AAS, including administration of epitestosterone and use of masking agents such as probenecid, 5α-reductase inhibitors, and diuretics.

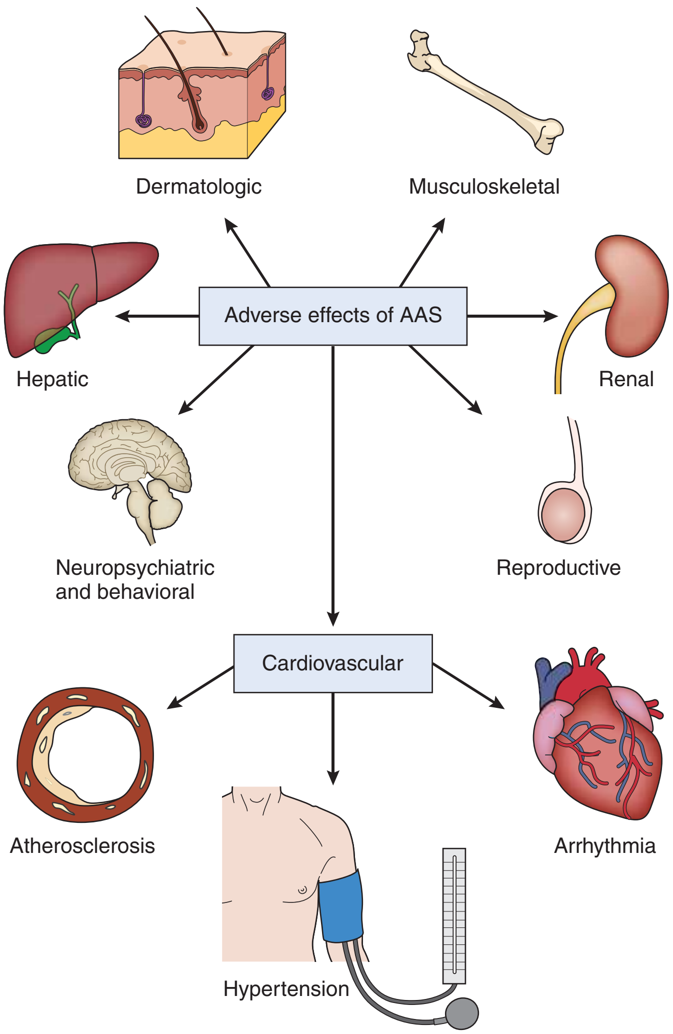

Figure 110.3 Adverse effects of anabolic androgenic steroids (AAS) by physiological systems.

HEALTH CONSEQUENCES OF ANABOLIC STEROID ABUSE

High-quality data on adverse health effects of AAS are scarce as there are no systematic prospective studies in individuals abusing AAS. Additionally, the current secrecy surrounding AAS abuse further confounds information from retrospective studies. Thus, the majority of the data on the adverse effects of AAS are derived from case reports, case series and cross-sectional case-control studies. Furthermore, there is evidence that many men who abuse AAS also indulge in other illicit drugs,[77] which could potentially contribute to the observed adverse effects. Additionally, these men often take high doses of dietary supplements and nutraceuticals that have not been carefully studied for safety or content.[77] As the widespread use of AAS in the general population only began 30 years ago, most abusers are still relatively young and may not have yet experienced adverse effects from AAS abuse.[78] Thus, most healthcare providers have not yet seen a large number of patients with complications of AAS abuse but will likely see them in their clinics as this cohort gets older. Below is the summary of the potential adverse effects of AAS across various organ systems (Fig. 110.3).

Cardiovascular

The AR is expressed in the human myocardium, vascular smooth muscle, and endothelium[79]; therefore, the abuse of AAS can have an impact on several aspects of human cardiovascular physiology. Indeed, a growing body of evidence supports that AAS abuse directly or indirectly impacts cardiovascular morbidity.

Blood Pressure: Supraphysiological doses of AAS have been associated with the incident or exacerbation of hypertension via multiple mechanisms. These include (1) inhibition of extraneuronal uptake of catecholamines,[80] (2) salt and water retention by inhibition of 11β-hydroxylase activity (which results in cortisol-induced activation of the mineralocorticoid receptor),[81] and (3) reduced aortic elasticity. Studies have shown that normalization of blood pressure after discontinuation of AAS may take up to a year.[82,83] To the contrary, some studies have not found such an association.[84] This lack of consensus is likely a result of the observational design and small sample size of these studies.

Dyslipidemia: AAS abuse is known to result in dyslipidemia. The most common observation is a 20% to 70% reduction in HDL cholesterol[85]; this reduction is more profound with the use of oral non-aromatizable AAS. In addition, HDL-mediated cholesterol efflux (a measure of HDL functionality) is also reduced in men who abuse AAS. This is important as HDL cholesterol efflux capacity is inversely associated with subclinical cardiovascular risk in young adults. Reductions in apolipoprotein A1[86] and increases in low-density lipoprotein (LDL) cholesterol and triglycerides have also been observed.[85] This atherogenic lipid profile may develop within a few weeks of AAS abuse and may take several months to resolve after their discontinuation.

Erythrocytosis: Erythrocytosis is the most common adverse effect of androgen use[87] and can result in increased blood viscosity and blood-flow resistance.[88] *In vitro* studies have shown a direct correlation between hematocrit and platelet aggregation. Mechanisms by which androgens stimulate erythrocytosis include stimulation of erythropoietin secretion, increasing iron availability by suppression of hepcidin, and direct stimulation of erythroid elements in the bone marrow.[89] Elevation of hematocrit above 52% may result in thromboembolic events.[85,90]

Myocardial Function: Long-term AAS abuse influences cardiac remodeling. Autopsy studies in young men who have abused AAS have shown left ventricle hypertrophy and increased overall cardiac mass.[91] These *post mortem* findings are corroborated by echocardiographic studies that show impairment of cardiac function in individuals with long-term abuse of AAS.[92,93] In a recent report, young men with at least 2 years of exposure to supraphysiologic doses of AAS had impaired systolic and diastolic function on echocardiography compared with experienced weightlifters reporting no exposure to AAS.[93] Cardiac dysfunction was worse in men who were still taking AAS at the time of evaluation compared with previous users, suggesting that discontinuation of AAS at least partially restores cardiac function (Fig. 110.4).[93] Systolic dysfunction with AAS abuse has also been observed by other authors.[92] However, as left ventricular hypertrophy is considered a physiologic adaptation to endurance and resistance training,[94–96] it is difficult to differentiate between the impact of exercise training versus the direct effect of AAS on this remodeling. Long-term exposure to high doses of AAS results in a decrease in myocardial contractile reserve to β-adrenoceptor stimulation,[97] which likely contributes to cardiac dysfunction. Furthermore, subtle histological changes in the myocardium as a result of AAS abuse are seen even before the onset of overt ventricular hypertrophy.[98]

Arrhythmias: Long-term abuse of AAS may lead to myocardial scarring and fibrosis even in individuals without coronary artery disease,[99] possibly by inducing cardiomyocyte apoptosis. Myocardial fibrosis alters cardiac electrophysiology predisposing to lethal arrhythmias.[100] Indeed, animal studies have suggested that nandrolone can potentiate the arrhythmogenic effects of cardiac ischemia by altering cardiomyocyte calcium handling. Arrhythmias in AAS abusers often occur during or shortly after physical activity[101] and include atrial fibrillation, supraventricular or ventricular tachycardia, and ventricular fibrillation.[102] Arrhythmias appear to be a common cause of sudden death in young AAS abusers, as some autopsy studies did not find evidence of either atherosclerosis or thrombosis in coronary arteries of these patients.[103,104]

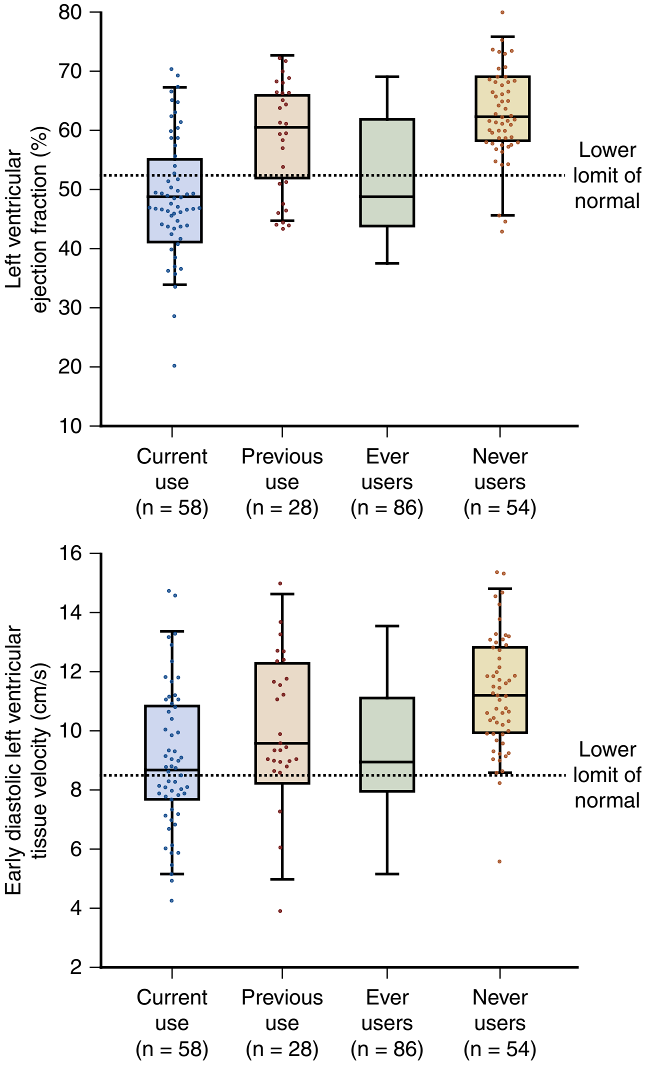

Figure 110.4 Left ventricular systolic and diastolic function in anabolic-androgenic steroid users and nonusers. (Adapted from Baggish AL, Weiner RB, Kanayama G, et al. Cardiovascular toxicity of illicit anabolic-androgenic steroid use. *Circulation* 2017;135:1991–2002.)

Atherosclerosis: Abuse of AAS has been associated with accelerated atherosclerosis. Men who abuse AAS have greater coronary artery plaque volume on computed tomography coronary angiography compared with nonusers, with greater plaque burden associated with cumulative AAS exposure.[93,105] These findings are corroborated by the numerous case reports of myocardial infarction in young men abusing AAS, which is likely a result of plaque rupture and thrombus formation.[91,106] Many cases of stroke in young AAS abusers have also been reported; however, most are thought to be due to embolic events.[107,108] Indeed, testosterone treatment has been shown to augment *ex vivo* platelet aggregability by increasing thromboxane A2 receptor density on human platelets.[109] Androgens also decrease production of prostacyclin, an inhibitor of platelet aggregation. Additionally, current AAS abusers have reduced fibrinolysis compared to nonusers and former users.[110]

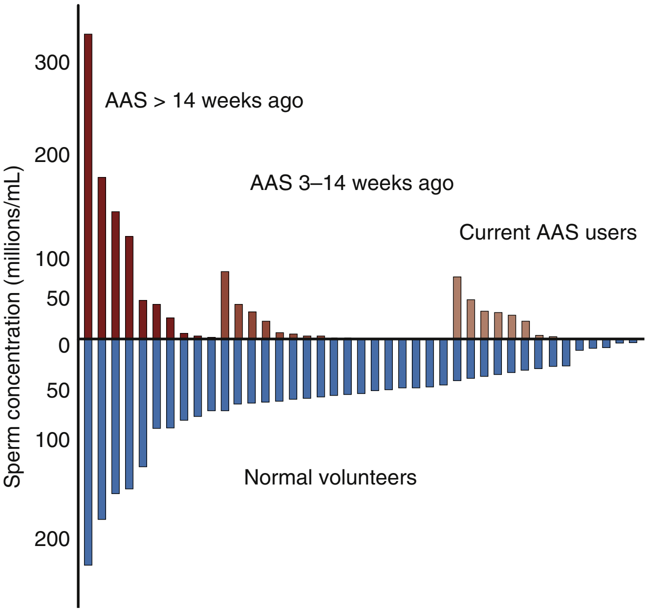

Figure 110.5 Sperm concentrations in 41 bodybuilders currently using anabolic androgenic steroids (AAS), those who discontinued AAS 3 to 14 weeks ago or discontinued >14 weeks ago *(red bars)* and in 41 drug-free volunteers *(blue bars)*. (Adapted from Nieschlag E, Vorona E. Mechanisms in endocrinology: medical consequences of doping with anabolic androgenic steroids: effects on reproductive functions. *Eur J Endocrinol* 2015;173:R47–R58.)

Reproductive

Considering that exogenous androgens suppress the HPG axis, it is not surprising that individuals involved in direct doping have suppression of testicular testosterone secretion and spermatogenesis. Although systematic evaluation of reproductive function in men who abuse AAS is lacking, data from studies of male hormonal contraception that used supraphysiologic doses of testosterone, usually in combination with a progestin, show profound oligozoospermia during the intervention phase.[111] Reassuringly, sperm concentrations returned to normal in 90% of participants within 12 months of cessation of intervention and in 100% within 24 months. The results of semen analysis in men abusing AAS show a spectrum that ranges from normal sperm count to azoospermia; the recovery of spermatogenesis is associated with time since last AAS (Fig. 110.5).[112,113] As the seminiferous tubules account for ~95% of the testicular volume, abuse of AAS often results in testicular atrophy. This explains why some AAS users choose to coadminister hCG to maintain testicular volume and spermatogenesis.

Sexual dysfunction is also a common adverse effect of AAS abuse.[78] As estrogens play an important role in male libido,[114] men who abuse nonaromatizable AAS experience low libido and erectile dysfunction as endogenous testosterone and estradiol are both suppressed. Additionally, even aromatizable synthetic AAS may not generate metabolites with similar estrogenic activity as estradiol, resulting in a detrimental effect on libido similar to nonaromatizable AAS. For these reasons, testosterone remains the most abused AAS, both among the athletes and general public. However, hypogonadism and sexual dysfunction are an integral part of the “AAS-withdrawal syndrome” that occurs upon discontinuation of all AAS,[115] and long-term abuse may result in prolonged androgen deficiency that may persist for months to years after discontinuation of AAS.[116]

Gynecomastia

Abuse of AAS may result in gynecomastia in some men, particularly those using aromatizable AAS in supraphysiologic doses. To prevent this, many men take ER antagonists or aromatase inhibitors. Gynecomastia is also seen in men who have persistent androgen deficiency after discontinuation of both aromatizable and nonaromatizable AAS.[117]

Hepatic

Hepatic adverse effects of AAS are generally limited to oral 17α-alkylated agents, such as methyltestosterone, methandrostenolone, oxandrolone, oxymetholone, and stanozolol. However, case reports of hepatic injury due to abuse of SARMs are emerging. The clinical assessment of AAS-induced hepatotoxicity poses some challenges. Rhabdomyolysis from high-intensity exercise can increase transaminases that may mislead clinicians into considering these elevations as a sign of hepatic injury.[78] To the contrary, AAS-induced hepatic injury sometimes does not result in an increase in transaminase levels.[118] Long-term use of 17α-alkylated agents reduces the activities of the microsomal drug-metabolizing enzyme system and the hepatic mitochondrial respiratory chain complex, and increases hepatic lysosomal hydrolases, without any increase in liver function tests. Macroscopic signs of AAS-induced hepatotoxicity are related to the cumulative dose and duration of abuse of 17α-alkylated steroids, and include cholestatic jaundice and hepatic peliosis (proliferation of sinusoidal capillaries that result in blood-filled cysts).[118] Data suggest that peliosis and hepatic adenomas are rare and not clinically apparent, with most cases found incidentally or on autopsy, although there have been rare reports of spontaneous hepatic rupture in men abusing AAS.[119]

Musculoskeletal

Compared with bodybuilders who do not abuse AAS, men abusing androgens have a much higher risk of tendon ruptures, mainly of the upper body.[120] This might be due to a rapid increase in skeletal muscle mass that outpaces adaptation by the connective tissues. This discrepancy in the speed of adaptation between the muscles and the tendons may also contribute to the higher patellar tendon stiffness observed in men with long-term AAS abuse. Some data also suggest altered metabolism of type-1 and type-3 collagen fibers in these men.[121]. Another important musculoskeletal adverse effect of AAS abuse is premature closure of the epiphyses in teenagers, which mainly occurs with the use of aromatizable AAS, resulting in reduced final height. Other musculoskeletal complications include myositis ossificans, a form of heterotopic ossification, that occurs at the site of intramuscular injections,[122] and generalized necrotizing myopathy, which rarely leads to severe rhabdomyolysis resulting in renal injury or multiorgan failure.

Renal

In addition to renal injury related to rhabdomyolysis, some cases of acute bile nephropathy secondary to AAS have been reported.[123] As previously discussed, oral AAS can cause cholestasis, increasing circulating concentrations of bile acids that lead to formation of bile casts in the renal tubules resulting in acute tubular injury; chronic exposure leads to progressive interstitial injury and tubulointerstitial fibrosis. Additionally, there have been reports of AAS-induced focal segmental glomerulosclerosis.[124] Though these serious forms of renal injury have been reported, the use of AAS generally presents as progressive subclinical deterioration of renal function. Indeed, a recent report that assessed creatinine and cystatin-C–derived estimates of glomerular filtration rate (eGFR) in weightlifters (57 current AAS users, 28 past users, and 52 never users) showed that eGFR was lowest in the current users, intermediate among the past users, and highest in nonusers.[125] Animal studies suggest that increases in oxidative stress and proinflammatory cytokines lead to renal cell apoptosis. Similarly, an increase in glomerular expression of CD34, a marker of endothelial dysfunction, has also been reported. Clinicians should be aware that higher muscle mass in these men is reflected by an increase in serum creatinine, which does not necessarily suggest impaired renal function. Thus, they should consider measurement of cystatin-C and its clearance to assess renal function.

Dermatologic

AR is expressed in the skin, and testosterone has been shown to dose-dependently increase sebum production.[126] Use of AAS affects the pilosebaceous unit and can lead to or exacerbate acne vulgaris and folliculitis; these conditions generally resolve upon discontinuation of AAS. Men abusing AAS may also develop *striae distensae* (stretch marks) due to the rapid increase in muscle size that outpaces expansion of the skin, likely due to reduced cutaneous elasticity as a result of AAS-induced reduced collagen production.[127] Keloid formation is also seen in some men.

Neuropsychiatric and Behavioral

Although there is a widespread notion that AAS abuse increases aggressive behavior, this is observed in a small number of individuals. In addition to experiencing neuropsychiatric symptoms during AAS abuse, androgen withdrawal is also associated with major depression, including suicidal ideation.[116] These mood changes might be related to a decrease in functional connectivity between the amygdala and the default mode network, as well as with other cerebral centers involved in control of emotions.[128] Moreover, reduced volumes of total gray matter, cerebral cortex, and putamen have been demonstrated in weightlifters with cumulative exposure to AAS of at least 1 year compared with weightlifters who never used androgens.[129] These data are also supported by preclinical studies showing that AAS induce neuronal apoptosis and reduce expression of nerve growth factor.

Dependence

Since the late 1980s, reports of dependence on AAS have been emerging, but only in recent years, these dependence syndromes have been widely recognized. Pooled data from 10 international studies suggest that 30% of AAS abusers may develop dependence—a prevalence much greater than seen for other recreational drugs.[16] Multiple factors likely contribute to the development of AAS dependence.[130] First, men with muscle dysmorphia may become "addicted" to AAS to maintain their physique as they fear losing muscle mass upon discontinuation of androgens. Second, AAS suppresses the HPG axis[115,116]; thus, upon discontinuation of AAS (especially after prolonged use), many men experience androgen deficiency. Recent data suggest that this androgen deficiency may persist for months or even years following cessation of AAS[116,131] and may result in sexual dysfunction, fatigue, and mood changes. Thus, many men resume AAS to avoid these adverse effects. Third, AAS may cause dependence via their hedonic properties. Although AAS use is not associated with intoxication that is associated with alcohol, opiates, or cocaine, their use is associated with feelings of self-confidence and "invincibility."[78] Animal data show that when male hamsters are given the opportunity to inject themselves with AAS via a nose poke device, they will self-administer AAS to the point of death.[132] This phenomenon has been demonstrated even in those animal studies where AAS were administered directly into the central nervous system, suggesting that the effects of AAS are central. All these factors might be responsible in predisposing men to dependence on AAS.

KEY POINTS

- Although high-quality data on adverse health consequences of AAS abuse are lacking, evidence from case reports, case series, and cohort studies suggest that AAS abuse may result in cardiovascular dysfunction, erythrocytosis, infertility, suppression of gonadal axis, gynecomastia, acne, and neuropsychological disturbances.

MANAGEMENT OPTIONS OF ANABOLIC STEROID ABUSE

Although the general principles of the medical management of AAS abuse are the same for both the elite athletes and the general public, there are some important differences that are highlighted in the section below.

Elite Athletes

Therapeutic Use Exemption: As in the general public, athletes may also have hormonal deficiencies for which they might be receiving appropriate hormone replacement. These include athletes with androgen deficiency due to organic diseases of the hypothalamus, pituitary, or the testes, such as Klinefelter's syndrome, chemotherapy-induced testicular injury, or central hypogonadism after hypophysectomy. For elite athletes participating in competitive sports in which AAS are prohibited, the process for obtaining permission to continue treatment from the relevant antidoping agency is known as Therapeutic Use Exemption (TUE). Clinicians, particularly endocrinologists, may be asked to verify that testosterone therapy is truly indicated for a particular athlete. The granting of a TUE for testosterone follows rigid guidelines, including documentation of specific signs and symptoms of androgen deficiency and unequivocally low morning testosterone concentrations on more than one occasion. For documented organic male androgen deficiency, the TUE after vigorous review can be granted for testosterone therapy and in some circumstances for gonadotropins.

If an elite athlete is found to be abusing AAS to purely achieve competitive advantage (i.e., not under TUE), the athlete is instructed to discontinue the use of the banned drug and may be blocked from competition for a proscribed period of time. These athletes are not given testosterone to mitigate the risk of AAS-withdrawal syndrome if they are still actively competing. On the other hand, a clinician may encounter retired elite male athletes who previously abused AAS while competing and now present with persistently low serum testosterone concentrations. Many of these men have low or inappropriately normal serum gonadotropins suggesting continued suppression of their HPG axis. The medical management of these retired elite athletes with hypogonadal symptoms is similar to members of the general public who have previously abused AAS (see below).

General Public

As there are no clinical trials on the management of long-term AAS abuse in the general public, care is based on the likelihood of severe withdrawal symptoms, the goals of the patient, and a risk-benefit analysis of the available treatment options.

Men Not Willing to Discontinue AAS: Some men who abuse AAS, either for competing in amateur sports or for image enhancement, are not willing to discontinue AAS. In this case, the main role of the endocrinologist is to ensure that the patient is fully informed about the known adverse effects of all types of AAS such as erythrocytosis, reduced fertility, dyslipidemia, and potential cardiovascular risks. Additionally, clinicians should counsel on the formulation-specific adverse effects of AAS (e.g., hepatotoxicity associated with 17α-alkylated steroids). In men who are already using supraphysiologic doses of testosterone, a prudent approach would be to gradually reduce the dose over the course of weeks to months to a physiologic replacement dose. This approach may help avoid severe symptoms of AAS withdrawal. On the other hand, men who are taking AAS other than testosterone could be switched to prescription testosterone. Based on the current dose of their AAS, replacement with testosterone can be initiated up to twice the usual replacement dose with a gradual taper to physiological dose over subsequent weeks. Anecdotal experience suggests that this approach (1) foments trust with the patient, (2) discourages purchase of AAS from unregulated sources, and (3) allows continuity of care with the physician. The clinician should continue to inform the patient that continued use of testosterone will result in continued suppression of the HPG axis.

Men Willing to Discontinue AAS: There are no randomized controlled trials comparing medical therapy versus no treatment on the degree of withdrawal symptoms related to discontinuation of AAS. Furthermore, available medical therapies are not Food and Drug Administration approved and are used in the clinics in an off-label fashion. For men who are willing to discontinue AAS, the management options include (1) discontinuation without additional medical therapy, (2) initiation of physiological testosterone replacement to avoid withdrawal symptoms (as mentioned earlier), and (3) short-term treatment with clomiphene or hCG. The selection of these options is dictated by the predominant reason that has led these men to discontinue AAS; in most cases, it is infertility. Clinicians should perform the usual workup indicated in the evaluation of infertility including measurement of serum testosterone and gonadotropins and perform semen analyses. If the working diagnosis of infertility is prior AAS abuse, then the choice of therapy is based on the couples' timeline for starting a family. If this is not an immediate goal, then the clinician could consider discontinuation of AAS with monitoring of serum testosterone and gonadotropins periodically. Once testosterone has normalized, serial semen analyses can be performed to assess resumption of spermatogenesis. This approach is based on the observation of spontaneous recovery of the HPG axis in trials of male contraception, where recovery of endogenous testosterone and spermatogenesis occurs within 3 and 12 months, respectively, after discontinuation of exogenous testosterone. Similarly, in men who have abused AAS for ≤1 year, recovery of the HPG axis occurs within a few months. To the contrary, among men who have abused high doses of AAS for >1 year, the recovery time is longer; such men might benefit from a short course of clomiphene or gonadotropin therapy after discontinuation of AAS.

Clomiphene Therapy: Clomiphene is a selective estrogen receptor modulator (SERM) that increases serum gonadotropins and testosterone concentrations within 2 to 4 weeks in men with an intact HPG axis.[133,134] Thus, the integrity of the HPG axis is a prerequisite for its efficacy. Limited data suggest that some men with a history of long-term AAS abuse experienced recovery of their HPG axis with clomiphene therapy.[135] The benefits of hastening the recovery of the HPG axis are of interest to men who are eager to have a child soon. Initiation of clomiphene at 25 to 50 mg every other day is a reasonable approach as it has been efficacious in normalizing serum testosterone concentrations. However, this benefit should be weighed against the potential side effects such as venous thrombosis and other cardiovascular events. The clinician should inform the patient that the safety and efficacy of this approach has not been shown in clinical trials.

hCG Therapy: Treatment with hCG is another option in patients with similar presentation. Subcutaneous hCG therapy stimulates testosterone production and spermatogenesis in almost all men with postpubertal hypogonadotropic hypogonadism. The increase in serum testosterone that results from administration of hCG suppresses gonadotropins; therefore, the HPG axis will remain suppressed after discontinuation of hCG. The usual dose of hCG is 1000 to 2000 IU subcutaneously 2 to 3 times weekly. The dose is adjusted until serum total testosterone is in the normal range and continued at least until conception. Data on the comparative effectiveness of clomiphene and hCG are lacking.

KEY POINTS

- Elite athletes abusing AAS should be advised to discontinue them, except in whom TUE has been granted.
- In the general population, men who abuse AAS and are unwilling to discontinue could be transitioned to physiologic testosterone replacement.
- Men who are willing to discontinue AAS could either be offered a drug holiday from testosterone, treatment with hCG, or a short-term trial with clomiphene (in an attempt to hasten the recovery of the gonadal axis).

CONCLUSION

The abuse of AAS continues to increase. Although legislative efforts have attempted to curtail access to these agents,[136] they continue to be easily procured through the Internet and other unregulated sources.[137,138] Although antidoping agencies tightly regulate doping among elite athletes, most men abusing AAS are not elite athletes but young men who want to enhance their image by improving their muscularity. Furthermore, the burden of adverse effects of these compounds will only become apparent when these men enter their middle age. Thus, tremendous amount of work needs to be done, including (1) organization of an education campaign to raise public awareness regarding the risks of AAS use, (2) collaboration between doping control laboratories and commercial laboratories to make doping tests available to clinicians, (3) creation of a steroid hormone user registry so that men abusing AAS can be followed systematically to assess doping practices and potential risks, and (4) clinical trials with ER antagonists and aromatase inhibitors to determine their efficacy in hastening the recovery of the HPG axis. This can be accomplished when patients, clinicians, researchers, and policy makers join hands and make a concerted effort toward achieving these objectives.

MACROSCOPIC ORGANIZATION OF THE ADULT HUMAN TESTIS

The adult human testis is 4- to 5-cm long, 15 to 35 mL in weight, enclosed on anterolateral and medial surfaces by serous membranes of the tunica vaginalis. Posteriorly, the associated epididymis and spermatic cord include the vas deferens and testicular neurovascular pedicle. Vessels and autonomic nerves from renal and abdominal aortic plexuses traverse the tunica albuginea, a 1-mm-thick, collagen-rich capsule deep within the tunica vaginalis.

The testicular artery enters posteriorly, descending to the inferior pole under the tunica albuginea to form the tunica vasculosa. In human testes, the main artery stem ascends beneath the anterior surface before smaller branches penetrate the parenchyma. Posteriorly, the thickened tunica albuginea projects into the testis parenchyma, forming the honeycomb-like mediastinum through which the rete testis links the testis seminiferous tubules via efferent ductules to the epididymis. Numerous imperfect, thin connective tissue septa extend from the tunica albuginea toward the mediastinum, creating several hundred incomplete pyramidal lobules containing the seminiferous tubules surrounded by loose connective tissue.

The Seminiferous Tubules

Spermatogenesis takes place within the seminiferous tubules; these are ~200 μm in diameter, ~600-m long, and occupy ~50% of the human testis volume. The numerous individual seminiferous tubules are highly convoluted linear segments. Each tubule ends in the mediastinum and empties via straight extensions, termed tubuli recti.[1]

The seminiferous epithelium is formed by contiguous Sertoli cells extending from the tubule base to its lumen. Fine and elaborate Sertoli cell cytoplasmic extensions envelope spermatogenic cells at all development phases. The most immature germ cells are mitotic spermatogonia that contact the tubule basement membrane. Spermatogonia undergo both self-renewing and multiplicative divisions, the latter with incomplete cytokinesis; clonal siblings are connected by cytoplasmic bridges through all subsequent differentiation steps. Spermatogonia differentiate and move away from the tubule base into the epithelium, forming the primary spermatocytes that commence meiosis. After the first meiotic division, these become secondary spermatocytes that undergo a second nuclear division to complete meiosis and become haploid round spermatids. Spermatids do not divide but undergo the complex metamorphosis called spermiogenesis. They are released into the tubule lumen as individual spermatozoa by the processes of spermiation.

Direct movement of substances between adjacent Sertoli cells is prevented by specialized tight cell junctions that also create basal and adluminal compartments in the seminiferous tubules. These junctions form the blood-testis barrier, which transiently opens as spermatogonia lose contact with the basement membrane to enter the adluminal compartment when they mature. Peritubular myoid cells completely cover the external tubule surfaces; together with the Sertoli cells, they synthesize the basement membrane that surrounds the tubules and upon which spermatogonia reside. These myoid cells contract irregularly to move sperm and Sertoli cell-secreted fluid in the tubule lumen through the mediastinum into the rete testis, which drains into the epididymis. Three successive rete testis zones are (1) straight tubules of the septal rete, (2) anastomosing mediastinal rete channels, and (3) wider extratesticular rete spaces that connect to the 6 to 12 fine efferent ductules that lead into the epididymal head.

The Intertubular Tissue

Adult human seminiferous tubules are surrounded by multiple layers of myofibroblasts, macrophages, and fibroblasts interspersed with collagen and extracellular matrix[1]; The peristaltic contraction and relaxation of peritubular myoid cells is governed by local vasoconstrictive and vasorelaxant products such as endothelin, vasopressin, oxytocin, and nitric oxide. Peritubular cells cosynthesize the tubule basement membrane with Sertoli cells, secreting proteins that modify the intratubular environment and directly affect spermatogenesis.[2]

The loose connective tissue of the interstitial area contains a species-specific cell composition. For example, the frequency and proportion of the androgen-secreting Leydig cells varies between species, typically occupying 10% to 20% of this area. Blood vessels occur randomly throughout the interstitium, and capillaries are nonfenestrated. Although lymphatic vessels and large lymphatic sinusoids exist in testes of several rodent species, in humans these reside only in the main connective tissue septa extending inward from the tunica albuginea. Because blood vessels do not enter the seminiferous tubules, germ cells embedded within the epithelium are dependent on Sertoli cells for direct support.[1]

Interstitial areas also contain fibroblasts and macrophages, both opposed to the tubules (peritubular macrophages) and also within larger spaces, usually adjacent to Leydig cells and blood vessels (interstitial macrophages). Lymphocytes and mast cells are less frequent and are typically more abundant near the tunica vasculosa. The macrophage and lymphocyte frequency and function relate to their roles in maintaining the testis as an immune-privileged organ.[3]

Postnatal Growth

Testis volume increases significantly from 1.1 mL (median paired testes volume) at 0 to 1 year of age, to 3 mL at 5 to 10 years, to 23 mL at 14 to 18 years, and reaching 40 mL in an adult group of 18 to 50 years.[4] Seminiferous tubule length per testis increases in prepubertal and postpubertal age ranges in a biphasic pattern, reaching a median length of 600 m in adults, with a wide variation that exceeds 1000 m in some individuals. The tubule diameter does not appreciably increase from birth to 14 years (50 to 60 μm) but expands to ~130 μm at 14 to 18 years and is ~200 μm in adults. Growth in seminiferous tubule length, but not diameter, in the prepubertal period reflects the significant increase in total germ cell numbers, from 13 to 83 million from 1 to 10 years of age, as spermatogonia populate the growing seminiferous tubules by migrating along the tubule length and forming more expansive colonies. This is followed by an exponential numerical expansion in the germ cell population.[5–7]

CELLULAR DEVELOPMENT AND ORGANIZATION FOR FUNCTIONAL CONTROL

The Spermatogenic Epithelium

Adult male fertility requires sustained proliferation and maturation of self-renewing germline stem cells and spermatogonial stem cells (SSCs) capable of differentiating into fully formed spermatozoa. The duration of one adult spermatogenic cycle (from stem cell to sperm) varies between species, taking 35 days in mice and hamsters, 50 days in rats, 45 to 65 days in several nonhuman primates, and 70 days in humans. The first release of spermatozoa (spermarche) in human puberty is at ~13.5 years of age, or earlier. Adult men produce ~1000 sperm per second, with 1.5 to 2.5 × 10^8 sperm typically present in an ejaculate.

KEY POINTS

- Spermatogenesis occurs with all germ cells embedded in the seminiferous epithelium created by Sertoli cells.

Germ cells occupy up to 75% of the seminiferous epithelium, arranged in multiple layers with least mature germ cells adjacent to the base and more mature cells closer to the tubule lumen. Maturing cells move apically through the epithelium connected as clonal siblings by cytoplasmic bridges until the most mature testicular germ cells, spermatozoa, are released into the tubule lumen (Figs. 111.1 and 111.2). This basal to luminal arrangement of maturing germ cells within the seminiferous epithelium is fundamentally similar in all mammals, although the associations between differentiating germ cell types along its length, termed *stages*, differ between species. Broadly speaking, regulation of adult spermatogenesis involves (1) endocrine stimulation of the testis by gonadotropins and steroid hormones (notably androgens), (2) local paracrine and autocrine factors, (3) tightly regulated gene expression within each germ and somatic cell type, (4) dynamic interactions between individual Sertoli cells and the changing variety of developing germ cells they support, and (5) Sertoli cell maintenance of the unique seminiferous tubule environment that restricts entry of cells, macromolecules, and immunogenic agents originating from the intertubular tissues and vasculature. Disturbance or impairment of any one of these parameters may disrupt or suppress spermatogenesis, contribute to defects in spermatozoa, and/or decrease sperm count.

Sertoli Cells

In the adult testis, Sertoli cells are the only nondividing cell type within the seminiferous tubules, and their function is central to sperm production. A single Sertoli cell partially or completely surrounds and supports several dozen or more germ cells.[8] The columnar Sertoli cell base rests on the basement membrane and overarches spermatogonia, extending apically to the lumen with elaborate lateral branches that interdigitate and surround all other germ cell types (Fig. 111.1). Each Sertoli cell contacts the base of five or six other Sertoli cells, simultaneously supporting up to 50 germ cells at different developmental stages.[9] Sertoli cells change shape as germ cells multiply, move, and undergo their own shape and size transformations. Sertoli cells divide only during fetal and postnatal life, stimulated by follicle-stimulating hormone (FSH), activin, and other factors; their number in an adult testis determines its spermatogenic capacity.[10] Proliferation during puberty occurs in species with a lengthy interval between birth and puberty, ending by approximately 15 years of age in humans.[11]

Blood-Testis Barrier. The blood-testis barrier exists in all animals. It is a structural and physiological compartment created by inter–Sertoli cell tight junctions on the luminal side of spermatogonia and their immediate descendants, the preleptotene/leptotene primary spermatocytes (Figs. 111.1 and 111.2). It includes several junction types, including tight junctions between adjacent Sertoli cell membranes that overlay a region of smooth endoplasmic reticulum with microfilaments projecting into the cytoplasm. The blood-testis barrier is stabilized by many intracellular components just beneath the cell membrane, including actin filaments and actin-binding proteins such as espin.[9,12] The junction positioning at the seminiferous epithelium base subdivides the anatomically and functionally distinct basal and adluminal compartments; spermatogonia develop within the basal compartment, while the meiotic and postmeiotic germ cells mature within the restricted adluminal compartment. Barrier integrity is essential for (1) excluding meiotic and postmeiotic germ cells from immunologic challenge arising from outside the seminiferous epithelium, (2) maintaining the stem and spermatogonial cell niche, (3) preventing intercellular fluid and macromolecular flow into the adluminal compartment and thus allowing its milieu to be determined by the Sertoli cells, and (4) enabling selective exposure of basal germ cells to regulatory factors originating from interstitial cells, such as Leydig and peritubular cells and macrophages.

The blood-testis barrier forms first in the peripubertal period when spermatogenesis is initiated by gonadotropic stimulation and coincides with the appearance of zygotene-pachytene primary spermatocytes.[13] Developing spermatocytes move through this tight junction barrier, which opens during their transit into the adluminal compartment and then reforms basally.[14]

In humans, junctional specializations between Sertoli cells are observed after 8 years of age and assembled in early puberty (11 to 13 years)[15] accompanied by increasing spermatocyte numbers. Coordinated signals by hormones (testosterone and FSH), retinoic acid (RA), and other factors differentially regulate tight junction dynamics to maintain blood-testis barrier integrity, yet allow germ cells to cross the barrier at the appropriate stage for meiotic maturation (see "Adult Sertoli Cell Function").

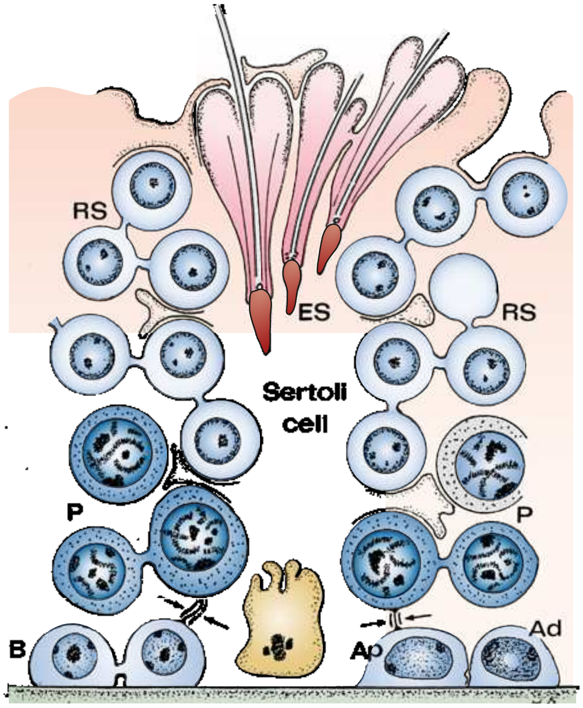

Figure 111.1 Diagram of the human seminiferous epithelium showing the general relationship between Sertoli cells and germ cells. Type A pale *(Ap)*, A dark *(Ad)*, and B *(B)* spermatogonia are shown in the basal compartment, together with primary spermatocytes *(P)*, early round spermatids *(RS)*, and elongating spermatids *(ES)* in the adluminal compartment. Inter–Sertoli cell tight junctions are indicated by *arrows*.

KEY POINTS

- The haploid spermatids undergo complex differentiation, termed spermiogenesis, involving sperm head nuclear compaction and acrosome development, sperm tail formation, cell organelle reorganization, and shedding of excess cytoplasm.

Plasticity and Links With Germ Cells. Concordant with elongated spermatid release at the end of spermiogenesis, Sertoli cells form specialized junctions with a new cohort of elongating spermatids and restructure inter–Sertoli cell junctions to permit spermatocyte translocation into the adluminal compartment (Fig. 111.3). The elaborate and dynamic cytoskeleton of adult Sertoli cells maintains their columnar shape, determines the distribution of its organelles, and mediates adhesion with germ cells. The cytoplasm around its nucleus contains microtubules and abundant motor proteins, dynein and kinesin, that are especially abundant in crypts surrounding elongating spermatid heads.[16] These cytoskeletal elements, together with intermediate filaments, are positioned to influence the dynamic shape and position of maturing germ cells as proceed through the spermatogenic cycle. Mouse models with defects in microtubule dynamics often exhibit phenotypes of premature germ cell release and sterility.

The actin-containing ectoplasmic specialization (ES) is another Sertoli cell cytoskeleton component that connects Sertoli and germ cells and facilitates spermatid orientation within the seminiferous epithelium. This structure in the Sertoli cells is positioned opposite the nucleus of newly elongating spermatids and facilitates their translocation in the epithelium as they elongate and develop an extensive flagellum.[17] The abundant Sertoli cell microtubular system moves spermatids by coupling its associated motor proteins to the ES. The microtubule-associated protein kinesin directs the

initial basal movement of elongating spermatids into deep Sertoli cell crypts, then the microtubule motor protein dynein reverses spermatid translocation, toward the lumen.[17] This transient penetration of elongating spermatids deep within the epithelium likely facilitates spermatid-Sertoli cell communication during spermiogenesis.

Phagocytosis, Endocytosis, and Secretion. Many germ cells are eliminated via apoptosis during normal spermatogenesis, and the spermatid residual cytoplasm remains within the epithelium as a residual body after spermiation. Sertoli cells process these apoptotic germ cells and residual bodies via phagocytic and endocytic pathways. Residual bodies move basally, while excess plasma membrane removal and luminal fluid absorption occur at the Sertoli cell apical cytoplasm.[18] Sertoli cells must also transport or generate metabolites required for germ cells in the adluminal compartment, as the blood-testis barrier prevents their direct delivery. Receptor-mediated endocytosis of macromolecules occurs at both apex and base of the epithelium, including to deliver iron from serum to germ cells.[19]

Spermatogonia and Spermatogonial Stem Cells

Spermatogonial proliferation and differentiation are regulated by hormones, paracrine/autocrine factors, and systemic nutrients.[20] The proliferative, sexually indifferent primordial germ cells formed in early embryogenesis adopt the male fate in response to somatic cell cues following *SRY* expression in Sertoli cells. Termed gonocytes, or prospermatogonia, in the fetal testis, they enter a period of mitotic quiescence then transform immediately after birth into mitotic spermatogonia in rodents or asynchronously in humans from fetal life to about 2 years. Fibroblast growth factor (FGF) signaling mediated by FGF8 helps initiate this transition by germ cells in late fetal life in mice[21]; transcripts encoding FGF receptors are present in human spermatogonia but their functionality is undetermined.[22] All spermatogonia undergo mitosis. Continuous production and release of spermatozoa requires a stable population of SSCs that either self-renew to generate more stem cells or produce progeny, which commence spermatogenesis and transform into sperm.

KEY POINTS

- The entire spermatogenic process involves highly regulated developmental steps, mediated by local and endocrine somatic cell products and requiring ongoing spermatogonial stem cell replication for continuous sperm production over the life span.

All spermatogonia are partly surrounded by Sertoli cells and also directly contact the basal lamina, so secretory products of peritubular tissues, Leydig cells, immune cells, and circulating factors including hormones can influence their maturation (Fig. 111.4). In adult mammalian testes, spermatogonia span a range of differentiation states that include the least differentiated SSCs, progenitor spermatogonia primed to differentiate but that can still form a stem cell pool, and the differentiated spermatogonia that cannot function as stem cells. Spermatogonia in mammals were originally classified into types A and B according to their nuclear chromatin patterns in histologic preparations.[23] Type A spermatogonia were classified into undifferentiated and differentiated subtypes, based on morphological criteria and their potential to function as stem cells,[24] and type B spermatogonia are those that divide to produce preleptotene spermatocytes. These categories and species-specific differences are being revealed by single cell transcriptome data (discussed later).

Transplantation analyses functionally identify SSCs as those germ cells that can reconstitute full spermatogenesis when transferred into a recipient testis. This can assess how specific signaling pathways contribute to SSC maintenance and differentiation, with one goal being the preservation or restoration of fertility for individuals undergoing stem cell–damaging chemotherapy.[25] Both organ and cell cryopreservation and culture are used for SSC preservation and recovery, and genetic modifications prior to transplantation can correct infertility-causing mutations in animals.[25] Transplantation of heterologous or xenologous germ cells has also revealed fundamental or conserved features of testis development. For example, rat or hamster germ cells undergo spermatogenic development in recipient mouse testes[26,27] with the rate of germ cell development intrinsic to the transplanted donor germ cells, rather than determined by the host niche. Mouse and other host testes will maintain human SSCs for months, but they do not differentiate[25]; however, allogeneic transplantation of Rhesus macaque spermatogonia into either juvenile or adult recipient testes can undergo complete spermatogenesis.[28] Thus autologous transplantation of preserved self-germline stem cells may enable men requiring chemotherapy to produce healthy sperm.

The prevailing model of the rodent spermatogonial hierarchy is based on markers for undifferentiated cell subsets and development of

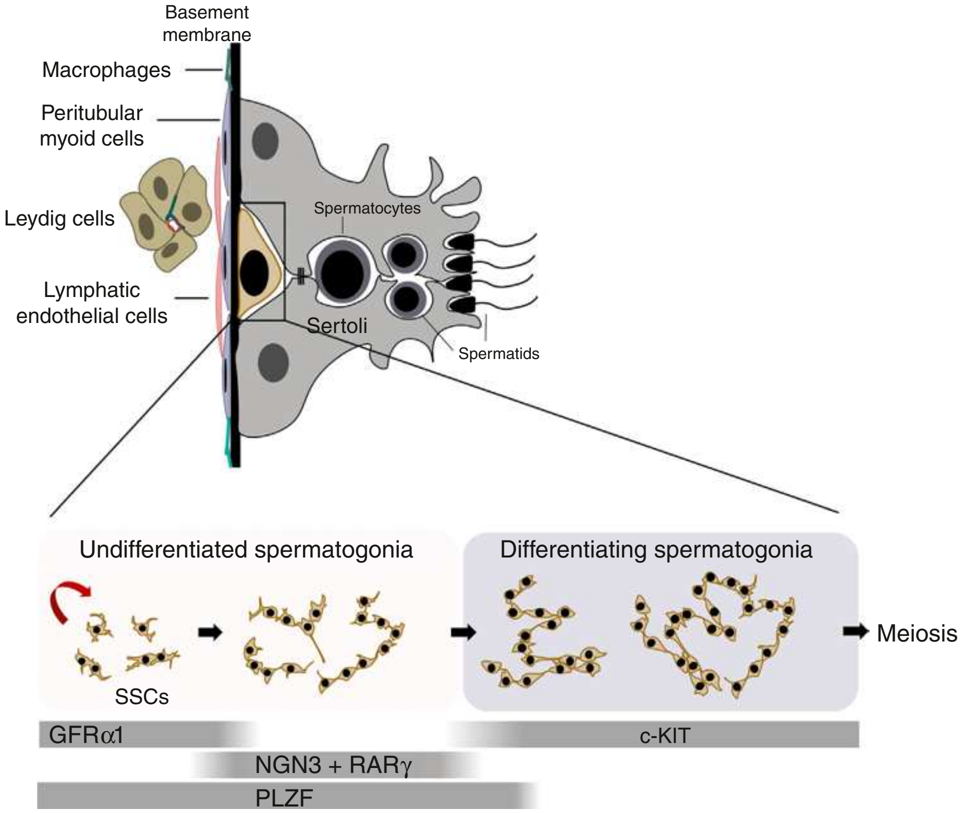

Figure 111.4 **Illustration of rodent spermatogonial hierarchy and components of the stem cell niche.** Spermatogonia are attached to the seminiferous tubule basement membrane and surrounded by multiple supporting somatic cell types *(top panel)*. A segment of the seminiferous tubule is shown. The spermatogonial population is divided into undifferentiated and differentiating fractions *(bottom panel)*. The undifferentiated population contains spermatogonial stem cells (SSCs) and differentiation-destined transit-amplifying cells. Differentiating spermatogonia undergo a series of coordinated mitotic divisions before generating meiotic spermatocytes that produce haploid spermatids. Molecular markers of the distinct spermatogonial fractions are shown.

functional SSC assays (lineage-tracing and transplantation).[20] It proposes that SSCs of the homeostatic testis are spermatogonia expressing the coreceptor for growth factor GDNF (GFRα1), which includes most single (A_s) and a substantial fraction of paired (A_{pr}) cells (Fig. 111.4). Transcriptional regulators ID4, EOMES, and PDX1 are linked to SSCs and are expressed within the GFRα1+ population.[29] GFRα1+ cells continually interconvert between syncytial states (A_{pr} plus short chains of aligned cells [A_{al}] and A_s through chain fragmentation).[30]

In contrast, undifferentiated cells positive for *Neurog3* (*Ngn3*), primarily longer chains (A_{al}), are destined to differentiate under the influence of RA acting via RA receptor γ (RARγ).[31] Spermatogonial differentiation is marked by KIT receptor induction and epigenetic changes, accompanied by loss of stem cell potential.[32] Importantly, Ngn3+ A_{al} can fragment to A_s and A_{pr} and contribute to the GFRα1+ stem cell pool, particularly under regenerative conditions, for example, following germline depletion or transplantation.[24] The role of transit-amplifying populations in germline regeneration was confirmed by studies of cells expressing *Piwil4* (*Miwi2*), a subset of the Ngn3+ population. Further, differentiation-primed progenitors can revert to an SSC state under the influence of niche factors such as GDNF, as demonstrated through culture and transplant-based studies.[29] Markers such as GFRα1, RARγ, KIT, and others are routinely used to functionally categorize spermatogonia (Fig. 111.4).[29]

Rodents have a distinct first round of spermatogenesis in which the first sperm arise soon after birth directly from gonocytes that transition directly into differentiating spermatogonia; all subsequent rounds of spermatogenesis derive from gonocytes that transition first into an undifferentiated spermatogonial state. Recent single cell-RNA sequencing (scRNAseq) analyses indicate that this is different in humans.[22,33] Human spermatogonia are maintained in one of two undifferentiated states in low numbers (States 0 and 1; 3% to 4% of all testis cells) from infancy through adulthood. This “reserve” population is amplified by multiplication at the onset of puberty, from 11 years; differentiating spermatogonia emerge (stages 2 to 4) with transcription of meiotic genes evident from 13 years.[22] Thus the mechanisms that control the initiation of spermatogenesis in juveniles are likely to be both shared and distinct between rodents and humans, and they may also be distinct from those active in adults.

The Spermatogonial Stem Cell Niche

The specialized stem cell niche microenvironment conveys extrinsic signals to modulate the intrinsic stem cell regulators that determine fate choice: between self-renewal, proliferation, differentiation, or cell death. Adult fertility requires an uninterrupted germ cell supply along the complete length of each tubule, and hence stem cells must be appropriately distributed. In the postnatal prepubertal rodent testis, spermatogenesis is initiated nonuniformly throughout the testis, with RA a fundamental driver for this in both neonatal and adult rodents.[34,35] Over time, complete cycles of the seminiferous epithelium are established with fairly precise spatial distribution along the tubules. Histological and real-time video evidence from rodent testes indicates that SSCs are nonrandomly positioned close to the vascular-rich intertubular regions rather than in regions where neighboring tubules are closely opposed; this distribution was reestablished if tagged tubule segments were freed of vessels and interstitial tissues subsequently transplanted into a recipient testis (Fig. 111.4). SSC density and localization are regulated by competition for limiting amounts of FGFs produced by lymphatic endothelial cells and other interstitial cells surrounding the tubules.[36] The Sertoli cell–produced chemokine, CXCL12, provides a critical signal via the CXCR4 receptor on SSCs, maintaining them in an undifferentiated state and controlling their homing to the niche.[37] CXCL12 may also influence the behavior of seminoma cells that arise in young men from fetal germ cells that fail to differentiate normally into spermatogonia.[37,38]

Glial cell–derived neurotrophic factor (GDNF) synthesis by Sertoli cells is essential for the maintenance and proliferation of mouse, rat, hamster, bull, and human SSCs. Its synthesis is stimulated by pituitary-derived hormone FSH and locally produced factors such RA, basic fibroblast growth factor (bFGF), tumor necrosis factor-α (TNFα), and interleukin 1b (IL1β).[39,40] Other cytokines including FGFs and colony-stimulating factor-1 (CSF-1) complement the role of GDNF in SSC renewal and proliferation[20] but how circulating factors affect their synthesis is unknown. Balanced signaling by WNT ligands and inhibitors (via both canonical β-catenin–mediated and noncanonical pathways) also contributes to SSC maintenance and differentiation.[20]

Morphological Features of Spermatogonia in Primate and Human

Type A spermatogonia are precursors of all further differentiated germ cells. Primate and human testes exhibit dark and pale type A spermatogonia. The A dark (Ad) spermatogonia stain deeply with hematoxylin and have homogeneous, fine chromatin with an obvious central pale-stained vacuole-type area. Pale type A (Ap) spermatogonia have uniformly pale-staining nuclei and one or two nucleoli near the nuclear membrane. Type B spermatogonia nuclei feature coarse, deeply stained heterochromatin clumps next to the nuclear membrane, with a central nucleolus.

Ad and Ap spermatogonia are in pairs and groups along the seminiferous tubule (see Fig. 111.2). Type Ad spermatogonia rarely divide in the human testis and are considered as reserve stem cells that only divide and transform into Ap cells after irradiation or cytotoxic treatment.[41] Type Ap spermatogonia undergo both self-renewing mitotic divisions and mitotic amplification as they transition into type B spermatogonia.[42] Type B spermatogonia divide by mitosis then become primary and secondary spermatocytes while undergoing the two nuclear cell divisions of meiosis to yield the round haploid spermatids that then transform into spermatozoa. In humans, the ratio of Ad spermatogonia:Ap spermatogonia:type B spermatogonia:spermatocytes is 1:1:2:4. The relationship of these morphologically defined populations to those identified by scRNAseq is yet to be revealed.

Spermatogonial Differentiation and Its Control

Application of scRNAseq to testes of different ages and in different species has identified the progressive expression of transcripts through their maturation, including those that encode signaling receptors and thereby reveal regulatory components that act successively. Common to both mouse and human spermatogonia is the delineation of sequential maturation states, transitioning generally from a more metabolically quiescent to active, replicative state, and acquiring machinery for meiosis.[43,44] The first two spermatogonial states in adult human testes (referred to as States 0 and 1) express stem cell–associated factors including *ID4* and *PLZF*, suggesting that they represent SSCs, while proliferation and differentiation-associated markers are upregulated in subsequent states (e.g., *KI67* and *KIT*, respectively).[33] State 0 cells most closely resemble germ cells of the immature infant testis, indicating they are more primitive than State 1 cells. Surprisingly, expression of *GFRA1*, an SSC marker commonly used in rodents, is predominately observed in State 1 spermatogonia, while State 0 cells, a potential quiescent reserve SSC population, are uniquely marked by transcripts such as *PIWIL4* plus *TSPAN33* and lacking in rodents.[33] However, in common with rodents, RNA-velocity analyses indicate that human spermatogonia can dynamically interconvert between functional states, and their transplantation potential is not restricted to the most primitive state.[33,45] This cellular plasticity is associated with limited changes in the epigenetic landscape between spermatogonial states.[33] Notably, markers of State 0 and 1 cells are expressed by both Ad and Ap spermatogonia, indicating the disconnect between transcriptional and histological cell features historically used to assess human spermatogonial functions[22,45]

Multiple signaling molecules produced by testis somatic cells that are known, and new ones predicted from scRNAseq analysis, support germ cells transitioning through spermatogenesis.[45] RA signaling is essential for spermatogonial differentiation in postnatal and adult testes. Induced RA deficiency in rats and mice through either dietary or pharmacological means reversibly arrests type A spermatogonial proliferation and differentiation.[34] Produced by Sertoli cells, RA represses *GDNF* transcription[40] and elevates transcripts associated with spermatogonial differentiation in both Sertoli (*Kitl* and *Bmp4*) and germ cells (*Stra8* and *Kit*). Activation of the KIT tyrosine kinase receptor via KITL (termed KIT ligand or stem cell factor [SCF]) from Sertoli cells is essential for survival and proliferation of differentiating spermatogonia.[46,47] This pathway is also central to human fertility; abnormal pathway component expression is documented in testes with defective spermatogenesis, and polymorphisms and mutations in *KIT* and *KITL* are frequently associated with infertility and testicular germ cell tumors.[48] The transforming growth factor-β (TGFβ) superfamily ligands BMP4 and activin A also influence spermatogonial differentiation, including by modulating levels of KIT, the hallmark of differentiating spermatogonia.[49] Additional factors affecting spermatogonial differentiation and proliferation include nerve growth factor, epidermal growth factor, and platelet-derived growth factor.

Also key for postnatal spermatogenesis is the doublesex-related transcription factor (DMRT1) involved with both Sertoli and germ cell development; *Dmrt1* deletion in mouse embryos resulted in azoospermic adults. Cell-selective deletion of *Dmrt1* in Sertoli cells prevented their postnatal differentiation and led to the loss of the male phenotype; deletion in germ cells impaired the initial establishment and subsequent maintenance of spermatogonia,[50,51] premature entry into meiosis, and eventual stem cell depletion. This outcome was dependent on vitamin A actions, including through direct interaction of Dmrt1 with genes encoding proteins required at the onset of meiosis such as Stra8 and the mitotic inhibitor p21Cip1.52 Mutations and single-nucleotide polymorphisms (SNPs) in *DMRT1* are implicated in human infertility and increased testicular germ cell tumor risk, with the latter implicating a germ cell–intrinsic defect as critical in the establishment of this condition in some men. As mentioned in "Genetic Defects", mutations in sex chromosomes may also affect spermatogonial proliferation and/or maturation.

Meiosis

Type B spermatogonia enter prophase of the first meiotic division to form primary spermatocytes. Sibling spermatocytes remain connected via the cytoplasmic bridges through which mRNAs and other macromolecules can transit.[53] Although these bridges first form as SSCs commence differentiation, their loss does not visibly impact progression until meiosis.[54] Meiosis involves a long prophase whereby DNA is replicated and there is homologous recombination between paired chromosomes to facilitate genetic diversity of the games. Preleptotene spermatocytes commence DNA synthesis, replicating each chromosome to form twin copies called *sister chromatids*, marking the commencement of prophase. As a consequence, the preleptotene primary spermatocyte chromosome number remains diploid, but the DNA content is 4C, twice that found in spermatogonia.

Prophase is subdivided into five phases based on gross chromosomal activities and appearance: (1) leptotene, thread-like chromosomes, (2) zygotene, homologous chromosome pairing, (3) pachytene, paired chromosomes thicken and undertake crossing over, (4) diplotene, paired chromosomes decondense and partially separate, and (5) diakinesis, chromosomes recondense. During prophase, homologous chromosomes pair and the *synaptonemal complex* facilitate the close apposition of each homologue pair, and the chromosomes form a synapse that permits crossover and exchange between them at *chiasmata*. Genetic exchange between the paired chromosomes requires error-free double-strand DNA breakage and repair; key to this is the strong upregulation in mid-phase primary spermatocytes of highly conserved topoisomerases.[55]

Metaphase follows prophase, as the highly condensed chromosomes align on a metaphase spindle. During anaphase, the chromosome pairs move to opposite poles of the cell. During telophase, complete nuclear separation forms daughter cell nuclei, producing *secondary spermatocytes*. The second meiotic division proceeds rapidly (<24 hours) without DNA replication, yielding two haploid spermatids, each with 1C DNA content. Thus four spermatids form from each primary spermatocyte. Errors during meiosis have severe consequences for fertility, ranging from azoospermia to oligospermia, to aneuploidy and elevated fetal loss.[56]

KEY POINTS

- Spermatogenesis features incomplete cytokinesis between clonal siblings, with mitosis in spermatogonia followed by meiosis in primary and secondary spermatocytes to achieve the haploid state.

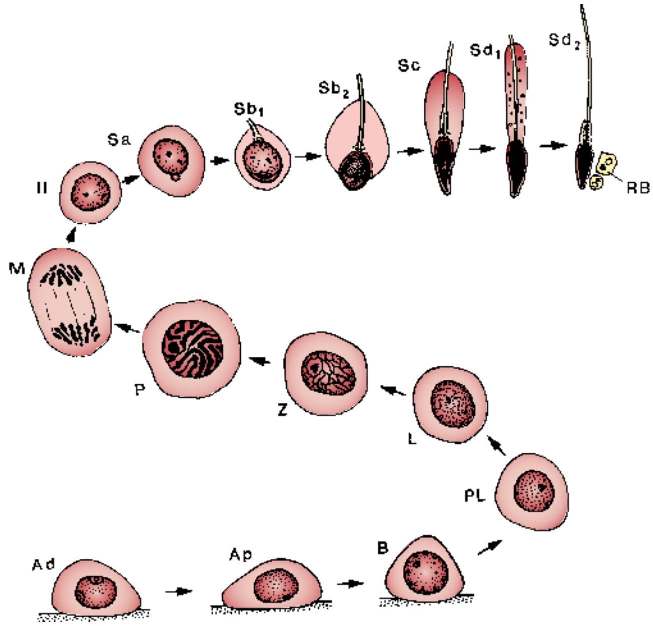

Figure 111.5 Sequence of germ cell types in human spermatogenesis commencing with a spermatogonium, progressing through an orderly sequence of cell proliferation and maturation, and terminating in a mature spermatozoon. Spermatogonia (shown on epithelial base): Type A dark *(Ad)*, A pale *(Ap)*, and B *(B)*; primary spermatocytes: preleptotene *(PL)*, leptotene *(L)*, zygotene *(Z)*, pachytene *(P)*, and meiotic division *(M)*; secondary spermatocyte *(II)*; spermatids *(Sa, Sb1, Sb2, Sc, Sd1, Sd2)*; residual body *(RB)*.

Spermiogenesis: Emergence of Spermatozoa

Spermiogenesis is the elaborate transformation of round haploid spermatids into elongated spermatozoa; it takes 24 days in humans (Fig. 111.5). Sibling spermatids remain connected by cytoplasmic bridges until their release into the tubule lumen at spermiation. The complex morphological features of spermatid maturation transform a spherical cell into the highly polarized spermatozoon, featuring a streamlined head containing a tightly compacted nucleus overlayed by the acrosomal vesicle, a tail for motility, and minimal cytoplasm (Fig. 111.6). The human spermatozoon head is spatulate in form and flattened, while the rodent sperm head is hooked or falciform. A thin membrane-bound cap, the acrosome, extends from the tip, or leading edge, of the head and covers approximately 60% of the sperm head. The nucleus is enveloped by a perinuclear theca, and the acrosome is attached to the apical pole via the acroplaxome.[57] The entire cell is covered by a plasma membrane. The complex assembly of the various components in each domain is a fascinating process that is heavily dependent on both actin- and tubulin-based cytoskeletal elements and their associated motor proteins (reviewed in[58]).

The Sperm Head. The sperm head contains the highly condensed haploid nucleus surrounded by a perinuclear theca enveloped at the apical end by the membrane-bound acrosomal vesicle containing enzymes and surrounded by the plasma membrane. The genomic DNA in sperm becomes compacted to occupy ~5% of the typical somatic cell volume in a highly regulated manner. Most histones are removed in developing spermatids and replaced first with transition proteins (TP1, TP2) and finally the protamines (1 and 2), retained in mature sperm. Acetylation of histones mediates their disassociation from DNA and subsequent ubiquitination, allowing histone replacement with the transition proteins that facilitate DNA compaction and the repair of DNA breaks arising during chromatin remodeling. Mouse data demonstrate the sequential incorporation of transition proteins, and protamines are absolutely required for normal fertility,[59] and altered protamine 1 and 2 ratios in sperm are associated with human infertility.[60] Protamines organize the spermatid genome into distinctive doughnut-shaped chromatin components. This exchange is incomplete, and approximately 10% to 15% of genes remain associated with histones in humans. Sites retaining nucleosomes are preferentially linked to early embryonic development and biased toward genes encoding transcription factors,[61] indicating that histone retention contributes to reproductive fitness.[62] Defects in histone retention or positioning may contribute to human infertility[61] and changes to ribosomal and genomic DNA methylation profiles in sperm correlate directly with aging.[63,64]

The onset of spermiogenesis requires a massive wave of transcriptional activity in haploid cells.[65] However, because nuclear compaction in elongating spermatids renders much of the genome inaccessible, RNA translation is regulated to ensure that proteins are synthesized at the appropriate time in late spermiogenesis. Translational regulation includes transcript storage in messenger ribonucleoprotein particles (mRNPs)[66] relating to particular sequences present in untranslated regions (UTRs), functions of small RNAs and a newly discovered class of abundance circular RNAs.[67]

Concordant with histone to protamine exchange, the sperm head species-specific shape is sculpted by the microtubule-based manchette. It forms as a girdle-like perinuclear ring in early elongating spermatids, with multiple microtubules extending toward the growing tail[58] and moving distally, facilitated by the kinesin-related molecular motor, KIFC1.[57] Nuclear shaping is aided by progressive manchette ring constriction involving cytoplasmic dynein.[68] Failure of manchette assembly or function results in teratozoospermia. Manchette microtubules also deliver essential components to the developing tail.[58]

While the sperm head is being shaped, the acrosome forms at the germ cell apical pole in four phases: Golgi, cap, acrosome, and maturation. Its assembly uses cytoskeletal machinery to incorporate membranes both

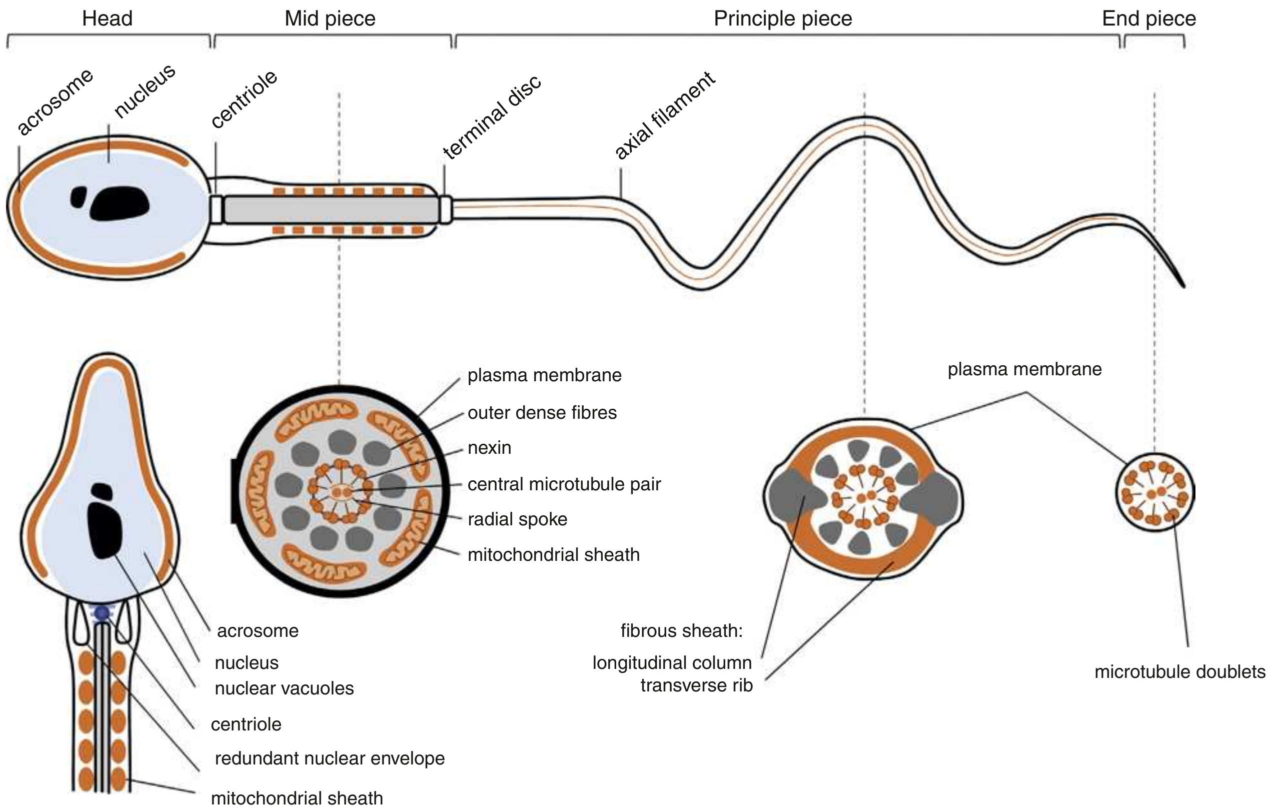

Figure 111.6 Diagram of a typical mammalian spermatozoan. Cross sections show distinct regions in the head and along the tail length, with 9 + 2 microtubule doublets forming the central axoneme.

from the Golgi and the plasma membrane.[58] The acrosome membranes and contents are regionally distinct, with the acrosome containing soluble proteins, including hyaluronidase and dipeptidyl peptidase, and an insoluble matrix containing proacrosin and proacrosin-binding protein. During fertilization, exocytosis of the acrosomal granule involves selective fusion of the apical, outer acrosomal membrane with the overlying plasma membrane, releasing soluble hydrolases required for sperm penetration through the oocyte vestments. Men in whom acrosome formation fails have globular-shaped sperm, termed globozoospermia, or sperm with misshaped heads (acrosomal hypoplasia), and they are infertile. In humans, mutations affecting several elements disrupt the connection between sperm head and tail and thereby cause infertility.

Another further key step in sperm head development is the assembly of sperm-oocyte receptor components, including by molecular chaperones.[69] Proteins required for or implicated in sperm fusion with the oocyte plasma membrane are mainly localized to the equatorial segment in acrosome-reacted sperm.[70,71] Post-testicular sperm modifications require dynamin proteins that mediate interaction with epididymosomes, vesicles secreted by cells lining the epididymis that preferentially localize to the post-acrosomal domain during epididymal transit.[72] This results in the gain of proteins and small nonprotein-coding RNAs that contribute significantly to fertility and offspring health.[73–75] Thus the appropriate formation and maintenance of complex sperm head domains and their dynamic modifications during post-testicular maturation are key for male fertility.

The chromatoid body, nuage, and intermitochondrial cement are important components of the maturing spermatid cytoplasm, where small RNAs (miRNAs and piRNA) and the machinery that produces them are transcribed and stored.[76] Circular RNAs (circRNAs) become predominant in elongating spermatids as templates for translation.[67]

The Sperm Tail. The complex sperm tail contains four structurally distinct regions: the neck or connecting piece, and the middle, principal, and end pieces (Fig. 111.6). The neck and head articulate at the nuclear caudal pole, with nine cross-striated columns continuous with the nine outer dense fibers (ODFs) extending the entire tail length. Within the neck core, the distal centriole remnant connecting the tail and head is the origin of the axoneme, the microtubule-based motility apparatus of sperm. The midpiece (~5-μm long in human sperm) comprises the axoneme encircled by nine ODFs, which is in turn surrounded by a mitochondrial sheath. More distally, the principal piece (~45 μm in human) contains modified ODFs that are partially replaced by the two fibrous sheath (FS) columns, connected by transverse ribs. The ODFs confer elasticity and have tensile strength integral to flagellar motility. Both ODF and FS taper along the sperm tail length, terminating at the end piece.

The sperm axoneme consists of nine outer microtubule doublets encircling two central microtubules, extending the entire tail length. Dynein arm projections from the outer microtubule doublets drive axoneme movement to facilitate sperm motility through coordinated ATP hydrolysis, based on anchoring between the axoneme and sperm head and between microtubule pairs 3 and 4.[58] The circular axoneme arrangement of nine microtubules, but lacking a central pair, is also present in motile cilia and flagella and in nonmotile nodal (in embryos) and primary cilia (on most nondividing somatic cells). Because of the fundamental importance of this conserved structure, male infertility and respiratory dysfunction are common features in ciliopathies arising from primary ciliary dyskinesia.[77]

Axoneme Growth and Composition. Axoneme growth commences in round spermatids from one of the pair of centrioles that initially lies close to the Golgi. The axoneme emerges from the distal, or mother, centriole, and the intact companion proximal (daughter) centriole is lodged within the neck cone at 90 degrees to the axoneme. The nine cross-striated columns of the neck are continuous with the nine ODFs (Fig. 111.6).

Axoneme development is concordant with sperm head elongation and condensation. Transcription of genes encoding sperm neck, ODFs, and FS components commences in early round spermatids and peaks during the acrosome phase.[78] Axoneme assembly requires conserved intraflagellar transport (IFT) processes for protein delivery and placement. The ODF forms from proteins in granular bodies in the periaxonemal cytoplasm in a proximal-to-distal direction along the full axoneme length. In contrast, FS proteins distributed in the caudal spermatid cytoplasm assemble in distal-to-proximal orientation along the axoneme, eventually overlapping with the ODF. In addition to its role in sperm head shaping, the manchette is implicated as a transport highway for proteins involved in sperm tail development, *intramanchette transport.*[58] Many of the more than 20 FS proteins are essential for fertility. Among these are specific A-kinase anchoring proteins (AKAPs), which position regulatory protein kinase A (PKA) subunits near appropriate substrates for tyrosine phosphorylation.[79]

The sperm midpiece terminates at the annulus, a septin-containing ringlike structure that restricts protein diffusion. Defects in annulus formation or positioning can contribute to infertility. The principal piece contains modified ODFs, and ODF-3 and ODF-8 are replaced by the longitudinal FS columns that are connected by transverse ribs. The ODF and FS taper along the length of the sperm tail and terminate at the end piece junction, so that the end piece solely consists of the axoneme surrounded by the plasma membrane.

The ODF and FS columns provide structural rigidity to sperm tail movement and protection against shearing forces. Species-specific oxidative phosphorylation by the mitochondria and ATP production in the FS via glycolysis are also required for axoneme function.

Release of Spermatozoa. At the end of spermiogenesis, spermatids undergo spermiation over several days[18] to separate from the Sertoli cell and become individual haploid spermatozoa. This begins at the start of the seminiferous cycle stage II in humans, with elongated spermatids aligned at the seminiferous tubule lumen. Key steps are (1) removal of the ES that anchors the sperm head to the Sertoli cell, (2) development and then dissolution of tubulobulbar complexes that both anchor germ cells and remove their cytoplasm, (3) residual body formation from excess germ cell organelles and cytoplasm, and (4) complete disengagement of spermatozoa from the seminiferous epithelium. See "Sertoli Cell–Mediated Regulation of Spermatogenesis" for an overview of sperm release regulation.

Germ Cell Associations and the Spermatogenic Cycle

The tight coordination of germ cell development within the seminiferous tubule is evident in both cross sections and whole-mount preparations. Tubule cross sections exhibit species-specific cell associations as consistent, co-located combinations of particular mitotic, meiotic, and haploid germ cell subtypes within the Sertoli cell epithelium. These repeat along the length of each tubule, in associations designated by Roman numerals as stages I to VI for humans. Over a period of days, a given point in the epithelium corresponding to an individual Sertoli cell harbors every stage in a repeating sequence. Individual stages may be several millimeters in length, reflecting simultaneous development of germ cell cohorts linked by cytoplasmic bridges.

The wave of the seminiferous epithelium cycle is defined as the time or distance along the tubule taken to progress through all germ cell stages. A complete sequence of 16 stages occupies a species-specific interval of days, referred to as one cycle of the seminiferous epithelium. Completion of spermatogenesis requires a spermatogonium to commence proliferation, pass through four cycles of the seminiferous epithelium, and transform into a spermatozoon. Xenotransplantation between rodent species shows this pace is endogenous to the germ cells (see "Spermatogonia and Spermatogonial Stem Cells"), while tissue grafts into mice demonstrate the host hypothalamic-pituitary axis can speed the initial development of monkey or pig germ cells.[80,81] In humans, one spermatogonium can yield a theoretical maximum of 32 spermatozoa,[82] while rodents can produce over 1000, due to undergoing 9 to 10 mitotic "amplification divisions" before meiosis commences.

Pachytene spermatocytes

Figure 111.7 Helical arrangement of germ cell development in human testis. Primary spermatocyte (leptone *[L]*, zygotene *[Z]*, pachytene *[P]*) positions drawn as strips that overlap and gyrate toward the tubule lumen. This pattern occupies only small seminiferous tubule segments, and elsewhere individual spermatogenic stages (I to VI) occur randomly along tubules.

While many species exhibit a single seminiferous cycle stage occupying each individual tubule cross section (Fig. 111.3), humans and some primates (baboon, crab-eating macaque, orangutan, chimpanzee) display several within the same sectioned tubules (Fig. 111.3). In some, but not all human tubules, the developing germ cell arrangement follows a series of overlapping helical strips (Fig. 111.7).[83] One relatively new set of criteria distinguishes 12 stages in the human spermatogenic cycle based on acrosomal morphology using immunohistochemical detection of proacrosin.[84] Findings from rodent models indicate that Sertoli cells determine the spatiotemporal patterning of the seminiferous epithelium cycle.

Spermatogenic Efficiency and Germ Cell Loss

Spermatogenic cell degeneration is a normal feature of testicular development and required for ongoing spermatogenesis; genetic ablation of cell death mediators in mice can cause infertility. Spermatogenic efficiency is defined as the theoretical versus actual yield of mature spermatozoa from a single SSC.[85] This species-specific number can be affected by external factors, such as seasonality, nutrition, infection, exposure to medication or environmental agents, or it may arise from genetically determined dysfunction. Up to 75% of the maximum predicted sperm yield is normally lost in some species. Apoptotic cell death in the testis, as in other tissues, balances cell proliferation and elimination for normal cell growth and population maintenance.[85] Germ cell apoptosis occurs in all phases of spermatogenesis in response to hormone deprivation, heat stress, radiation, antimetabolic agents, cytoskeletal disrupters, cytotoxic agents, and tumor-inducing drugs. This mediates the removal of mitotic germ cells that harbor unrepaired DNA, spermatocytes with chromosomal breaks or unequal chromosomal exchange, and germ cells too numerous or inadequately supported by Sertoli cells.

Distinct from necrosis, apoptotic cells fragment and form condensed bodies that include the pyknotic nucleus. Importantly, these bodies do not lyse and thus do not provoke an inflammatory response; instead, they are phagocytosed and their contents "recycled," typically by the Sertoli cells. Homodimers or heterodimers of Bcl-2 family proteins either promote (Bax, Bak, Bcl-x_s, Bad) or prevent (Bcl-2, Bcl-x_L, Bcl-w, Mcl, Al) apoptosis; their relative proportions determine whether apoptosis proceeds. Bcl-2 family expression is regulated during spermatogenesis, with spermatogonia requiring Bcl-w for survival.[86] Apoptosis is triggered by cysteine protease caspase activation, causing sequence-specific protein cleavage. Caspase 2 synthesis in germ cells establishes a sustainable balance of germ cells relative to niche size in the first spermatogenic wave, while caspase 9 and BAX mediate germ cell degradation following torsion-mediated ischemia in adults.[87] Sertoli cell engulfment of apoptotic mouse germ cells is required for ongoing spermatogenesis.[88]

Genetic Defects and Spermatogenesis

Knowledge of genetic contributions to idiopathic spermatogenic disruption in men is being expanded by analyses of large population datasets and new technologies[89]; this topic is addressed in Chapter 115. Mutations in over 450 genes can cause male infertility in mice, and many correspond to known genetic changes that impair human fertility.[90] Genetic causes include aneuploidies, with Klinefelter's syndrome (XXY) most frequent, chromosomal translocations, large chromosome deletions, particularly of the Y chromosome, copy number variations, and point mutations. In addition to human sex chromosome mutations that underpin 10% to 20% of male infertility cases,[91] extrinsic factors affecting chromosomal integrity, including exposure to oxidative stress, are implicated in up to 40% of male infertility cases.[92]

Epigenetics in the Male Germline

Chemical modifications to gDNA and histones determine which genes are open for transcription factor access and which are closed and silent. Transmission of this epigenetic information from parent to offspring occurs in gametes and can affect multiple generations.[93,94] Essential reprogramming of primordial germ cells involves global gDNA epigenetic erasure; this provides a "blank slate" for regulating transcription of genes needed in development that are later switched off in differentiated cells.

Methyl group addition to cysteine residues in gene promoter CpG islands (5-methylcytosine [5mC]) can silence their transcription, mediated by DNA methyl-transferase enzymes. During cell replication, DNMT1 transfers 5mC to maintain the parental cell transcription profile. However, *de novo* methyltransferases DNMT3A, DNMT3B, and DNMT3L act in fetal life to remethylate of germline precursor cell gDNA following their unique genome-wide demethylation. Histone modifications include acetylation, methylation (at lysine or arginine), or phosphorylation of histone tails.[93]

Epigenetic inheritance can depart from traditional Mendelian inheritance of one allele from each parent for every gene. Instead, a critical, parental-specific imprint can silence either the maternal or the paternal allele in certain genes. These imprints must be erased in the primordial germ cells for correct inheritance of parental epigenetic information; maternally imprinted genes must be demethylated in the male offspring's germline in which only paternal imprinted genes will be remethylated, and vice versa for the female germline.[94]

Retrotransposons are mobile DNA elements that have the potential to excise themselves from the genome, copy and paste themselves back into host cells, and thus can create new mutations. Occupying up to 40% of the human genome, their movement within a genome is usually suppressed by the same type of methylation marks that create closed chromatin structures. However, during the period of global demethylation in primordial germ cells, their gDNA is vulnerable to retrotransposon activity. Specific PIWI/piRNA pathway components are crucial for repression of retrotransposons during *de novo* methylation in fetal life. The P-element–induced wimpy testis (PIWI) proteins in the Argonaute family of RNA-binding proteins are highly expressed in germ cells.[95] PIWI proteins cleave and destroy mRNAs transcribed from transposons sequences; this cleavage creates the PIWI-interacting RNAs (piRNAs) that bind PIWI proteins then cooperatively silence transposons. In postnatal life, the PIWI/piRNA pathway regulates genes required for male fertility and many other cellular processes essential for life. Key components of this pathway essential for spermatogenesis are PIWIs, Tudor-domain containing (TDRD) proteins, DNMTs, and piRNAs.[96] The transcription factor A-MYB (MYBL1) drives transcription at loci encoding these "pachytene piRNAs," facilitating their biogenesis in early pachytene spermatocyte development,[97] though the trigger for this is unknown.

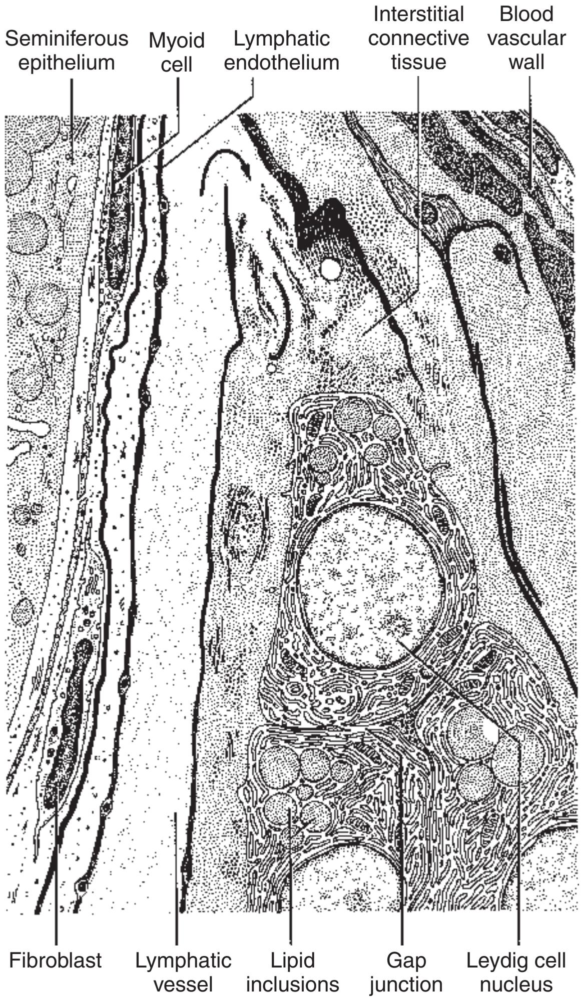

Figure 111.8 Cellular arrangement with the testis intertubular tissue, observed by electron microscopy to illustrate organelles and lipid droplets. (From de Kretser D, Kerr J. The cytology of the testis. In: Knobil E, Neill JD, eds. *The Physiology of Reproduction*. 2nd ed. New York: Raven Press; 1994:1177–1290.)

THE INTERTUBULAR COMPARTMENT

The space between seminiferous tubules is occupied by a loose connective tissue containing Leydig cells, macrophages, blood and lymphatic vessels, and the testicular innervation (Fig. 111.8).

KEY POINTS

- Spermatogonia are the only germ cells directly contacting the extratubular environment consisting of blood vessels, immune cells and fibroblasts, testosterone-producing Leydig cells, and the circulating gonadotropic hormones, follicle-stimulating hormone and luteinizing hormone.

Leydig Cells

Fetal, immature, and adult-type Leydig cells are epithelioid in shape. Their basophilic staining property arises from abundant smooth endoplasmic reticulum, where enzymes catalyze steroidogenic conversions, most notably conversion of acetate or cholesterol into testosterone. Leydig cells also contain Golgi membranes, microtubules, mitochondria with tubular cristae (unique to steroidogenic cells), peroxisomes, and scattered rough endoplasmic reticulum. Lipofuscin pigment granules are prevalent in human Leydig cells.

Other Interstitial Cells

The intertubular tissue contains abundant resident macrophages, characterized in several species using histochemical, immunologic, and ultrastructural techniques. Testicular resident macrophages have anti-inflammatory and tolerogenic properties, allowing tissue allografts or xenografts survive for long periods in recipient rodent testes[98]; consequently, the testis is designated as one of the rare immunologically privileged organs.

The mesenchymal or fibroblast-type cell populations in intertubular tissue are a source of new Leydig cells. These Leydig precursor or stem cells reside in peritubular and perivascular locations; they can produce testosterone following stimulation by luteinizing hormone (LH) and ultimately differentiate into Leydig cells.[99]

THE IMMUNOLOGIC ENVIRONMENT OF THE TESTIS

Germ cells excluding spermatogonia and very early spermatocytes develop within the adluminal testis compartment, isolated from the intertubular environment by the tight inter–Sertoli cell blood-testis barrier junctions. This sequesters more mature germ cells from the systemic immune system. Immune cells are normally confined to the testis intertubular tissue and include resident macrophages, antigen-presenting dendritic cells, circulating lymphocytes and significant numbers of CD8+ cytotoxic T cells and natural killer (NK) cells, and immunoregulatory T-cell subsets.[100] Interactions between resident and circulating immune cells are considered to regulate testicular immune responses and facilitate immune privilege.

KEY POINTS

- Spermatocytes and spermatids develop within the Sertoli cell intratubular epithelium that provides their structural and nutritional support and forms the blood-testis barrier that creates an immunologically privileged environment essential for fertility.

In early observations of the rat, functional interactions between Leydig cells and macrophages were deduced from their intimate association via specialized cytoplasmic interdigitations.[101] Testicular macrophage secretions including cytokines and steroidogenic precursors have the potential to regulate steroidogenesis by Leydig cells. Moreover, inflammation-like responses induced by Leydig cell hyperstimulation with the LH agonist, human chorionic gonadotropin (hCG),[102] implicates the close association between Leydig cells with macrophages in intratesticular inflammatory responses involving mast cell secretion, polymorphonuclear leukocyte infiltration, and in increased blood flow, capillary permeability, and interstitial fluid accumulation.

The heterogeneous resident macrophage population comprises two main subsets defined by shape and distribution: ovoid intertubular macrophages close to Leydig cell clusters and blood vessels, and flattened peritubular macrophages with dendritic-shaped projections, directly adjacent to the tubules.[103,104] Most resident macrophages arise from the fetal yolk sac and liver, although many details of their origins and maintenance remain to be fully elaborated.[105] Testicular macrophages are crucial for normal testis somatic and spermatogenic development.[103]

ENDOCRINE AND LOCAL CONTROL OF SPERMATOGENESIS

Interactions Between the Testis, Hypothalamus, and Pituitary Gland

After puberty and in adults, control of testicular function is exerted by the hypothalamic-pituitary axis through episodic secretion of the gonadotropic hormones FSH and LH from the pituitary. These are in turn regulated by the pulsatile secretion of gonadotropin-releasing hormone (GnRH) from the hypothalamus into the pituitary portal vessels. Testosterone production by Leydig cells is regulated by LH acting via specific receptors. The secretion of GnRH, FSH, and LH is modulated by negative feedback from the testis via testosterone and by the Sertoli cell product, inhibin.[106] Testosterone, estradiol, and dihydrotestosterone (DHT) can suppress pituitary LH secretion.[107] Testosterone primarily acts at the hypothalamus by decreasing GnRH pulse frequency without changing pulse amplitude.[107] Thus although the seminiferous tubule and intertubular testis compartments may be considered separately, their functions are intimately related through paracrine and endocrine control mechanisms. The stimulatory actions of FSH and testosterone on seminiferous tubule function are modulated by local factors.

Inhibin is a dimer of an α and a β subunit, synthesized by males almost exclusively in Sertoli cells,[106] with inhibin B, an α:βB dimer, the predominant form in adult human testes. Inhibin secretion by Sertoli cells is directly related to FSH stimulation,[108] and serum inhibin B levels are used as a noninvasive marker of Sertoli cell number and function.

The activin proteins are produced throughout the body as dimers of inhibin β subunits that affect many cellular processes. Activins stimulate pituitary FSH production and are produced in the testis by spermatogenic, Sertoli, and Leydig cells and by macrophages where it acts on spermatogonia, spermatocytes, round spermatids, and Sertoli cells.[109] Many proteins that regulate activin signaling are produced in a highly regulated manner during spermatogenesis, including its potent inhibitor, follistatin.[110] Activin A drives Sertoli cell proliferation, and thereby contributes to determining the spermatogenic capacity of the testis; its overproduction can lead to tumor formation.[111]

In the fetal mouse testis, HSD17B1 and HSD17B3, the enzymes that convert androstenedione into testosterone, are synthesized in Sertoli cells in response to activin A.[112] Thus mouse fetal Leydig cells can only produce androstenedione, and circulating activin A levels may profoundly affect fetal hormone production, a relationship currently unexplored in the human fetal testis. LH stimulation of Leydig cells is central to normal pubertal onset.[113] It rapidly stimulates cholesterol mobilization and increases testosterone levels within 30 to 60 minutes of LH stimulation. Particularly in human, a repeated LH stimulus or a single hCG injection, which has a longer half-life, generates a prolonged testosterone response.[114]

Testosterone, the major adult Leydig cell androgenic product, enters the circulation through nearby capillaries. Testicular cells produce smaller amounts of weaker androgens, including androstenedione and dehydroepiandrosterone, and small amounts of DHT, which binds the androgen receptor with high affinity and generates ~25% of circulating 17β-estradiol.[115]

CONTROL OF SERTOLI CELL FUNCTION

The potential adult spermatogenic output of a testis is determined by its number of Sertoli cells.[116] As the nurse cells to developing sperm, Sertoli cells have receptors for the main hormonal regulators of spermatogenesis, functioning to “transduce” FSH and androgens signals to support germ cell development.

Sertoli Cells During Fetal and Postnatal Development

Sertoli cells are specified in early fetal life following expression of male sex determining genes, *Sry* and *Sox9* in mice.[116] They migrate from the coelomic epithelium into the nascent gonad and form the seminiferous cords as they envelope and direct masculinization of the primordial germ cells, which become gonocytes or prospermatogonia. Together with the fetal peritubular myoid cells, they secrete the extracellular matrix components that surround spermatogenic cords and form the basement membrane upon which spermatogonia ultimately reside. Because the cords later transform into adult testis seminiferous tubules, Sertoli cell proliferation during fetal life is a key determinant of future testis size and fertility, and this is stimulated by activin A from fetal Leydig cells. Activin, FSH, and androgens affect other Sertoli functions,[117] including synthesis of AMH required for Müllerian duct regression[116] and testosterone from the Leydig cell–derived androstenedione.[112,118] Endocrine disruptors, including environmental chemicals and pharmaceuticals, and lifestyle factors, such as diet and smoking, can restrict fetal testis development, including via effects on Sertoli cells.[119]

Many Sertoli cell products support gonocytes.[120] The enzyme CYP26B1 facilitates primordial germ cell masculinization by removing RA, degrading this trigger for meiosis. Platelet-derived growth factor (PDGF) and Notch signaling enhance gonocyte proliferation, while TGFβ, activin A, and testosterone each promote their entry into quiescence.[121] Intriguing evidence of cyclic functionality in fetal Sertoli cells suggests that these are a heterogeneous population.[122]

Sertoli cells proliferate through early postnatal life. In humans, fetal-neonatal proliferation increases their number ~5-fold, and a second prepubertal wave more than doubles it.[123] FSH and thyroid-stimulating hormone (TSH), and local products activin A and insulin-like growth factor, each stimulate postnatal Sertoli cell proliferation.[10]

Sertoli cells cease proliferation when puberty sets the upper limit for adult sperm production. As Sertoli cells “switch” to a mature phenotype, they acquire the capacity to support spermatogenesis, changing from PI3K/AKT/mTORC1 and MEK/ERK1/2 signaling pathways that promote proliferation to cyclic adenosine monophosphate–stimulated pathways for differentiation.[124] These are influenced by insulin-like growth factors, including relaxin,[125] and the interplay between RA and activin, collectively allowing formation of tight junctions between Sertoli cells.[10] Other endocrine and local products, including androgen, estrogens, and TSH, and exposure to exogenous agents such as inflammation and endocrine disrupting chemicals are implicated as affecting the timing of this switch and tight junction integrity.[10] Testis function during the pubertal transition in primates is discussed by Bhattacharya and colleagues.[126.]

Roles and Clinical Significance of Androgen and FSH in Sertoli Cell Development and Establishment of Spermatogenesis

Spermatogenesis is first established in conditions different from those present in adults. Both FSH and androgens are required for quantitatively normal spermatogenesis in rodents and primates, with roles that differ between species.[127,128] Androgen and FSH act independently, cooperatively, and synergistically to support establishment of spermatogenesis,[127] while RA produced in the seminiferous epithelium governs spermatogenic cycle initiation and drives germ cell meiotic entry.[129]

Cooperative actions of androgens and FSH on testicular somatic cells create an optimal germ:Sertoli cell ratio during the first spermatogenic wave in rodents, with proapoptotic factors balanced by FSH support of spermatogenesis.[117]

The rodent and primate studies establishing that both androgen and FSH are needed for optimal postnatal spermatogenic development have informed clinical therapies. Men with congenitally acquired or prepubertal onset hypogonadotrophic hypogonadism require coadministration of hCG or LH (stimulates Leydig cell androgen production) and FSH (stimulates Sertoli cell proliferation and maturation). In some men, treatments of 1 to 2 years may be required to allow for testis maturation and 64 days for sperm production from spermatogonia.[130]

Adult Sertoli Cell Function. The adult Sertoli cell is extraordinarily complex in terms of its cytoskeletal organization, polarity and bidirectional secretion, ability to rapidly and cyclically respond to the changing needs of the germ cells as they progress through their development, and its capacity to respond to endocrine and paracrine “cues” from the vasculature and adjacent somatic cells (see “Sertoli Cell–Mediated Regulation of Spermatogenesis”). For a comprehensive review on this extraordinary cell, refer to *The Sertoli Cell* book[131]; however, a few aspects of adult Sertoli cell function are discussed briefly here.

RA is a particularly important regulator of adult Sertoli cell function. It is cooperatively generated from dietary-derived retinol in the circulation via enzymes present in Sertoli and germ cells in the postnatal seminiferous epithelium.[129] RA actions in the testis are regulated via a complex interplay between enzymes that produce RA, storage and binding proteins that direct RA toward either classic RA-mediated or alternative PPAR-related signaling pathways, and enzymes that degrade RA. Specific roles of RA in germ cell development are detailed below (see “Sertoli Cell–Mediated Regulation of Spermatogenesis” and Fig. 111.9). Importantly, RA drives Sertoli cell cyclic function,[129] with vitamin A deficiency reversibly blocking spermatogonial differentiation and Sertoli cell cyclic behaviors in rodents[129]; RA produced by advanced germ cells contributes to regulation of the Sertoli cell, potentially explaining how transplanted germ cells control the cycle in the host niche.[27] This may involve enzymes other than the well-known ALDH1A enzymes.[132] Thus the Sertoli cell cycle, or “clock”, that arises during testis development is “set” by RA signaling and partially maintained by germ cells in the adult testis.[129]

Each adult Sertoli cell produces many components required by the stage-specific cohorts of spermatogenic cells it supports,[65] including lactate, the preferred substrate for germ cell glycolysis, metabolized from glucose. The dynamic junctions between Sertoli and germ cells required for adhesion and intercellular communication include desmosome-like, gap and adherens junctions with spermatogonia and spermatocytes, and the ESs with elongating spermatids.[133] The blood-testis barrier comprises inter–Sertoli cell junctions (Fig. 111.3) that are constantly remodeled in mid-spermatogenic stages to permit translocation of leptotene spermatocytes into the specialized milieu of the apical epithelium. Formation, maintenance, and remodeling of this barrier is regulated by androgens and FSH (see below), and it is locally regulated by paracrine factors that affect endocytosis and many signaling pathways, for example, by RA, activin, and TGFβ ligands.[13] In particular, RA and activin A appear to coordinate adult inter–Sertoli cell junction remodeling, with activin-promoting junction disassembly and RA-promoting junction assembly.[13]

Roles and Clinical Significance of Androgens and FSH in Adult Sertoli Cell Function. In adult mammals, androgens and FSH are both required to maintain quantitatively normal spermatogenesis. The functions of androgen and FSH on spermatogenesis are executed via receptors in Sertoli cells, although androgen also acts via AR in other testicular somatic cells.[127] The hormonal regulation of spermatogenesis has been addressed in Chapters 105–107, the requirement of gonadotropins for adult sperm production is the basis for hormonal male contraceptive development. A brief summary of the major actions of androgens and FSH to support adult spermatogenesis and their clinical significance is provided below.

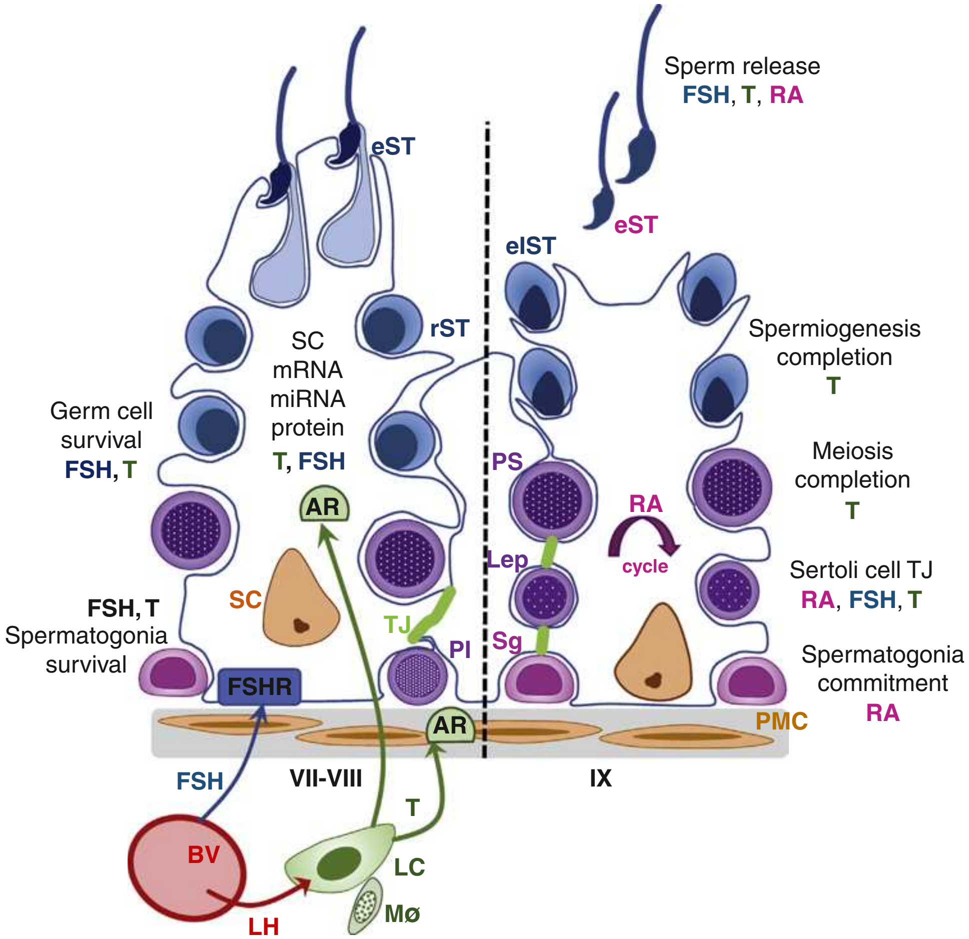

Figure 111.9 Overview of the regulation of spermatogenesis by follicle-stimulating hormone *(FSH)*, luteinizing hormone *(LH)*/testosterone and retinoic acid *(RA)*. *VII, VIII, and IX* denote the stages of the spermatogenic cycle represented in the diagram; *AR,* androgen receptor; *BV,* blood vessel; *elST,* elongating spermatid; *eST,* elongated spermatid; *FSHR,* FSH receptor; *LC,* Leydig cell; *Lep,* leptotene spermatocyte; *MØ,* macrophage; *Pl,* preleptotene spermatocyte; *PMC,* peritubular myoid cell; *PS,* pachytene spermatocyte; *rST,* round spermatid; *SC,* Sertoli cell; *Sg,* spermatogonia; *T,* testosterone; *TJ,* Sertoli cell tight junctions.

Withdrawal of gonadotrophic support, and the resulting suppression of testicular androgen production, suppresses sperm output and results in spermatogenic defects in adult rodents or primates, with variation between species[127] and dependence on the extent of gonadotropin suppression. In general, acute or long-term gonadotropin suppression in adults results in reduced spermatogonial entry into spermatogenesis, deficient blood-testis barrier function, reduced germ cell viability, particularly of pachytene spermatocytes and round spermatids in the mid-spermatogenic stages, and reduced ability of germ cells to enter meiosis or complete spermiogenesis or spermiation[127,128] (Fig. 111.9).

These processes have different thresholds for gonadotropin and androgen support. For example, in rodents, suppression without complete elimination of intratesticular testosterone prevents round spermatid maturation beyond mid-spermiogenesis, whereas the absence of androgen action on Sertoli cells due to genetic ablation of Sertoli cell AR blocks progression of meiosis by halting Sertoli cell functions that support the germline meiotic initiation transcriptional program.[134] Different spermatogenic defects arise from acute and long-term gonadotropin withdrawal. In primates, which are particularly sensitive to gonadotropin levels, acute suppression causes spermiation failure and alters spermatogonial kinetics, whereas long-term suppression is associated with a failure of spermatogonia to progress through spermatogenesis.[135]

Androgens and FSH synergize to support adult spermatogenesis, probably due to their overlapping influence on Sertoli cell signaling and gene transcription.[136] However, whether androgens and FSH have independent effects is a key, long-standing question. Spermatogonial development has a particular requirement for FSH, whereas meiosis is thought to absolutely require androgens.[127,128] Mice with a constitutively and strongly activated FSH receptor that lack an LH receptor do maintain sperm production, albeit reduced, even when residual testicular androgen action is blocked.[137] Thus very high FSH levels/receptor activation can compensate for a lack of LH/androgen in terms of stimulating fertility, suggesting that elevated FSH activity could stimulate androgen-dependent signaling pathways in Sertoli cells, despite their use of entirely different receptors.[137]

An acute and consistent suppression of both LH and FSH is the basis for hormonal contraception in men. Many different formulations have been trialed to promote maximum gonadotropin suppression while maintaining peripheral androgen actions, with some formulations showing particular promise.[138] The variability in individual responses is a key challenge: not every man shows adequate and consistent sperm count suppression, perhaps due to innate differences in the testicular response to gonadotropin withdrawal.[138] Additionally, the speed of sperm count suppression can vary, perhaps depending on whether or not a man shows an acute arrest of spermiation.[139]

Aspects relating to treatment of infertility are discussed in Chapter 112. Briefly, in terms of spermatogenic stimulation in men with infertility due to insufficient gonadotropin production (hypogonadotrophic hypogonadism) post-puberty, men are often treated with hCG (as an LH substitute), frequently in conjunction with FSH, for several months until sperm counts increase.[140] While hCG alone can stimulate spermatogenesis in some men, a combination of hCG and FSH administration is often administered to achieve optimal sperm production.[140]

Sertoli Cell–Mediated Regulation of Spermatogenesis. Sertoli cells coordinate the main endocrine signals from the HPG axis to stimulate and maintain spermatogenesis, and androgen and FSH receptors within Sertoli cells are necessary for optimal germ cell development.[128] The absolute dependency of germ cells on Sertoli cells was shown by diphtheria toxin (DTX) administration to transgenic mice expressing DTX receptors in Sertoli cells that caused their ablation.[141] This approach demonstrated that Sertoli cells (1) actively maintain peritubular myoid cell fate during development, (2) support adult Leydig cell and progenitor cell development and maintenance required for testosterone production, and (3) maintain the testicular vasculature structure and function central to Leydig cell steroidogenesis[142] (reviewed in 141). By showing that selective adult Sertoli cell ablation determines germ and Leydig cell numbers,[143] the DTX model unequivocally demonstrated that adult Sertoli cells determine both sperm output and androgen production.

RA signaling in Sertoli cells operates at a specific point in the spermatogenic cycle (also see "Adult Sertoli Cell Function") to coordinate multiple events and stimulate the spermatogenic "wave" (Fig. 111.9). RA signaling regulates spermatogonial commitment to germ cell entry into meiosis, blood-testis barrier remodeling, and elongated spermatid release at spermiation, events that occur in mid-spermatogenic stages corresponding to stages II-III in humans and VII-IX in mice. Their coordination may be achieved by local regulation of RA production and degradation between stages VII and IX, resulting in a pulse of RA signaling at VIII, which triggers RA-responsive processes (reviewed in 129).

The Sertoli cell creation of a stem cell niche and support for spermatogonial development are described earlier in this chapter (*Spermatogonia and Spermatogonial Stem Cells*).

Support of Meiosis and Spermiogenesis. Germ cells physically begin meiosis when type B spermatogonia divide to produce preleptotene spermatocytes.[127] The commitment to the meiotic program is made in rodents with differentiation of A to A1 spermatogonia, regulated by a pulse of RA in mid-spermatogenic stages and dependent on the RA-induced gene *Stra8* in mice.[129]

Preleptotene spermatocytes transition into leptotene spermatocytes as they traverse the inter–Sertoli cell junctions into the adluminal compartment where meiosis is completed[14] (Fig. 111.9). Junction remodeling facilitates meiotic progression, involves a multitude of adhesion and related signaling molecules (reviewed in 13) and is responsive to FSH, testosterone, RA, and activin signaling in Sertoli cells (see "Adult Sertoli Cell Function" and Fig. 111.9).

The completion of meiosis takes several weeks and depends on a complex transcriptional program that involves post-transcriptional regulation of mRNA stability via the "Meiosis Specific With Coiled-Coil Domain" (MEIOC) protein.[144] RNA sequencing has revealed the complex meiotic transcriptional program,[33] which is sensitive to androgen deficiency. When androgen levels or action are suppressed, meiosis can occur and spermatids are reduced; however, complete ablation of androgen action in Sertoli cells arrests spermatogenesis prior to meiotic division,[127] showing that round spermatid production absolutely requires androgen signaling (Fig. 111.9).

Pachytene spermatocyte and round spermatid survival requires hormonal support.[127] Some apoptosis of these cells occurs during normal spermatogenesis, and they are removed by Sertoli cells via phagocytosis and autophagy-related processes regulated by an androgen-dependent miRNA essential for normal fertility.[145]

Importantly, defects in meiosis and spermiogenesis observed in rodent models of hormone manipulation are not recapitulated in gonadotropin-suppressed monkeys and men. This is because the spermatogonial entry into meiosis in primates is exquisitely sensitive to gonadotropin suppression,[127] and thus monkeys and men undergoing gonadotropin suppression predominantly exhibit arrested spermatogonial development, likely due to reduced germ cell survival.

Sperm Release. The final step in testicular germ cell development is spermiation, whereby elongated spermatids are released into the tubule lumen for transport and further maturation in the epididymis (reviewed in 18). The involvement of a multitude of cytoskeletal and adhesion proteins and signaling cascades in Sertoli cells renders it highly vulnerable to disruption.[18,146] It is one of the first spermatogenic processes to be altered by FSH and androgen suppression and RA inhibition (Fig. 111.9), and it is also responsive to changes in estrogen production and signaling.[18,146] The initial phases involving spermatid translocation and adhesion structure removal are particularly vulnerable to altered RA signaling.[146] Changes in estrogen activity impair tubulobulbar complex formation required to remove the ES junctions between spermatids and Sertoli cells.[146] FSH and androgen actions on Sertoli cells are involved in mediating the final spermatid release via a FAK-integrin–based adhesion complex. Defects within spermatids can also prevent their release from Sertoli cells.[18] The consequences of acute defects in spermiation can significantly reduce sperm counts, an important response to hormone-based contraceptives.[18]

Control of Spermatogenesis: Challenges Ahead

Increased fundamental knowledge of the processes that underpin development of the healthy testis and fertile sperm are vital to address clinical and agricultural needs. The transgenerational effects of sperm on offspring health demand that information about spermatozoa formation and function is used to inform best practice in industrial, farming, and clinical settings. Delineation of epigenetic and genetic effects on germline formation at each life stage is critical, with species-specific and conserved impacts requiring evaluation. Current extensive reliance on artificial reproductive technologies and development of fertility preservation techniques, coupled with an ongoing demand for new male contraceptive approaches continues to underscore the need for research-based evidence of how spermatogenesis is controlled.

Summary and Future Directions, 1888

INTRODUCTION

In this chapter, we will consider the prevalence and common causes of male infertility. We will briefly describe environmental factors that may impact sperm production and development. Lastly, though not in clinical use, we will discuss the exploratory research on epigenetic regulation of spermatogenesis, as these epigenetic modifications may not only influence the reproductive health of the man but also his progeny. This chapter should be read in conjunction with chapters on Regulation of Spermatogenesis (see Chapters 111 and 113).

DEFINITION AND PREVALENCE OF MALE INFERTILITY

The World Health Organization (WHO) defines infertility as "a disease of the reproductive system defined by the failure to achieve a clinical pregnancy after 12 months or more of regular unprotected sexual intercourse."[1] However, it should be noted that many men with male infertility due to defects in spermatogenesis are otherwise healthy. Thus whether male infertility is a disease is debatable but conditions with a pathophysiological basis should qualify and be treated as a disease.[2] The main factors influencing spontaneous conception are the duration of unwanted infertility, the age of the female partner, and disease-related infertility (e.g., known chromosomal anomalies, testicular diseases, and hypogonadotropic hypogonadism).[3] Infertility affects about 15% of couples. Males are solely responsible for about 20% to 30% of the infertility and contribute to about 50% (ranges between 20% in sub-Saharan Africa and 70% in Middle East) of all cases of infertility globally. A meta-analysis of the global prevalence indicates that 2.5% to 12% of men in the general population are infertile. The prevalence is estimated to be 8% to 12% in Central/Eastern Europe, 9% in Australia, 7.5% in Europe, 4.5% to 6% in North America, and 2.8% to 5.7% in sub-Saharan Africa and 8.5% to 11.7% in North/West Africa.[4] Causes of this regional variation in male infertility rates in the general population are not known and may be subject to reporting errors.

KEY POINTS

- Male factors are solely responsible for about 20% to 30% of infertility and may be a factor in 50% of all cases.
- Male infertility rates differ in different geographical regions of the world.

COMMON CAUSES OF MALE INFERTILITY

While many men with male infertility have oligozoospermia (decrease in number of sperm cells in the ejaculate compared with reference range) or azoospermia (no spermatozoa in the ejaculate), some infertile men have normal sperm concentration. The generally accepted reference ranges for fertile men in the WHO Manual for the Examination of and Processing of Human Semen[5] are shown in Chapter 12 (Table 12.3). The data were based on semen samples of over 1941 fertile men whose partners had a time to pregnancy within 12 months.[6] Azoospermia occurs in about 16% of infertile men presenting at infertility and andrology clinics.[7,8] Over 80% of men with infertility have low sperm concentration (oligozoospermia) that may be associated with a decrease in sperm motility (asthenozoospermia) and a decreased percentage of spermatozoa with normal morphology (teratozoospermia). Others do not have low sperm concentration but may have qualitative defects in sperm motility, abnormal sperm morphology, and/or function. The common causes of male infertility are categorized into: (1) hypothalamic-pituitary disorders; (2) spermatogenesis defects with low sperm concentration or absent spermatozoa; (3) abnormal sperm motility, morphology, functional defects, and/or genetic incompetency; (4) posttesticular duct obstruction; and (5) idiopathic (unknown origin). In each category, the cause can be congenital (usually due or ascribed to possible genetic defects) or acquired (Table 112.1).[9] There is currently a large number of infertile men categorized as unknown or idiopathic infertility. With modern genetic analyses tools, many of these men may be shown to have a genetic cause of infertility although environmental factors may also contribute.[10] The frequency of the causes may vary between regions and Table 112.1 shows the common causes of infertility based on data from andrology and reproductive medicine clinics.[7–9,11]

Hypothalamic-Pituitary Disorders

Any hypothalamic or pituitary disease/dysfunction may cause gonadotropin-releasing hormone (GnRH) or gonadotropin deficiency (hypogonadotropic hypogonadism) presenting with secondary male hypogonadism (testosterone deficiency) associated with infertility. These conditions are characterized by low serum concentrations of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and testosterone. In a large andrology clinic, hypothalamic-pituitary disorders occur in 1% to 2% of infertile men.[8,11] It is important to diagnose hypogonadotropic hypogonadism, as there are specific therapies available (pulsatile GnRH or gonadotropins). These conditions can be subdivided into congenital or acquired disorders (see Chapters 105 and 106).

KEY POINTS: Hypothalamic-Pituitary Disorders

- Hypothalamic-pituitary endocrine disorders (with low serum testosterone) represent a small percentage of overall cases of male infertility.
- Congenital hypogonadotropic hypogonadism can be due to defects in the development and migration of the GnRH neurons (Kallmann syndrome associated with anosmia and other developmental defects) or in impaired GnRH secretion or action (GnRH receptor defects) not associated with olfactory anomalies. Congenital hypogonadotropic hypogonadism undergoes spontaneous remission in 10 to 20% of patients (both adolescents and adults).
- Other genetic defects such as gonadotropins and gonadotropin receptors are very rare.
- More common acquired hypothalamic-pituitary disorders are sellar and suprasellar lesions: pituitary adenomas, craniopharyngiomas, meningiomas, lymphocytic hypophysitis, Rathke's cleft cysts, germinomas, and drugs (opioids and androgenic steroids) and severe systemic illness.
- Since specific therapies are available, it is important to diagnose these disorders

Congenital Hypogonadotropic Hypogonadism (Table 112.2)

GnRH Neurons Development or Migration Defects (Associated With Anosmia/Hyposmia). Patients with isolated congenital hypogonadotropic hypogonadism (cHH) have defective GnRH production or secretion, low LH and FSH levels, and present with delayed puberty (see Chapters 102 and 103). Genetic defects can be identified in over 40% of cHH using current gene panel screening methodologies.[12,13] The genes associated with cHH can be subdivided to those that are associated with GnRH neuron development and/or migration (Kallmann syndrome) with anosmia or hyposmia or those associated with defective GnRH secretion (normosmia) or action. Many heterogeneous genetic mutations cause cHH (Table 112.2) and the mutations can be digenic or oligogenic.[14] Genetic analyses may help to distinguish between cHH and constitutional delayed puberty.[15,16] About 10% to 20% of patients with cHH undergo spontaneous remissions after testosterone treatment suggesting a functional defect or misclassification of patients with delayed puberty. For this reason, endocrinologists may elect to withdraw hormone replacement therapy periodically in adult and adolescent patients diagnosed with cHH to assess for recovery.[17] Kallmann syndrome, the X-linked form, is due to mutations of *ANOS1* (*KAL1*) and hypogonadism is associated with anosmia or hyposmia and midline facial defects such as harelip and cleft palate and unilateral kidney agenesis. Other genetic defects that cause cHH include fibroblast growth factor 1 receptor *(FGFR1)* or *FGF 8*, and prokineticin 2 (*PROK2*) and its receptor (*PROKR2*) that may present clinically with a spectrum of findings including anosmia to normosmia, midline defects, and skeletal and dental abnormalities. Gene mutations of chromodomain helicase-DNA-binding protein 7 (*CHD7*) are part of the CHARGE syndrome (coloboma, heart disease, choanal atresia, retarded growth and development/central nervous system anomalies, genital anomalies/hypogonadism, and ear anomalies/deafness) and patients may have anosmia to normosmia.

GnRH Secretion Defects (Normosmia). There are many genes involved in GnRH secretion, mutations of which result in cHH in males. *KISS1* and *KISS1R* genes encoding kisspeptin 1 and kisspeptin 1 receptor regulate GnRH secretion and onset of puberty. Activating mutations of *KISS1* are associated with precocious puberty, whereas disrupting mutations of *KISS1R* lead to cHH.[18,19] Mutations of the leptin (*LEP*) and leptin receptor (*LEPR*) genes result in extreme obesity and cHH. Another important regulator of GnRH secretion is neurokinin B (NK3R) that encoded by the gene *TAC* and mutations of *TAC3* and its receptor *TACR3* results in cHH and delayed puberty. *PCSK1* gene product protein convertase subtilisin/kexin-type 1 processes several precursor hormones (proinsulin, proopiomelanocortin) to release bioactive hormones. Mutations of *PCSK1* are associated with obesity and cHH. DAX-1 encoded by *NROB1* is important for the development of the adrenals and hypothalamic-pituitary-gonadal axis. NROB1 mutations result in adrenal insufficiency and cHH.[10]

GnRH and Its Receptor. Mutations of *GnRH* gene are very rare but mutation of its receptor gene (*GnRHR)* results in cHH with normosmia and accounts for 3.5% to 16% of sporadic cHH and over 40% of familial normosmic cHH.[13,20]

LH and LH Receptor; FSH and FSH Receptor Defects. LH gene mutations are very rare and the patient will present with delayed puberty, cryptorchidism, and hypogonadism. LH receptor gene inactivating mutations have variable presentation from female phenotype to only male infertility similar to androgen receptor defects. Mutations of FSH or FSH receptor result in variable phenotypes from azoospermia to normal spermatogenesis.[21]

Acquired Hypogonadotropic Hypogonadism. Acquired hypogonadotropic hypogonadism may be associated with other pituitary hormone deficiencies (see Chapter 106).

Tumors. The commonest tumors associated with hypogonadotropic hypogonadism are pituitary macroadenomas, microprolactinomas, craniopharyngiomas, or meningiomas. Hypogonadotropic hypogonadism often persists in men with macroprolactinoma even after treatment with dopamine agonists and serum prolactin concentration normalized. After surgical or radiation therapy of either macroadenomas or craniopharyngiomas, hypogonadotropic hypogonadism often ensues.

Infiltrative Diseases. Infiltrative diseases include sarcoidosis, histiocytosis, tuberculosis, fungal infections, transfusion-related hemosiderosis,[22] and hemochromatosis (a genetic disorder of mucosal iron transport that results in increased deposition of iron in many tissues including the pituitary gland). Hemochromatosis-associated hypogonadotropic hypogonadism is nearly always of postpubertal onset.[23,24]

Lymphocytic Hypophysitis or Infundibulitis. This autoimmune condition affecting the pituitary and/or the infundibulum results in enlargement of the pituitary gland. Lymphocytic hypophysitis or

TABLE 112.1 Common Causes of Male Infertility

Congenital (Genetic)	Acquired (Nongenetic)
Hypothalamic-Pituitary Disorders	
• **Congenital hypogonadotropic hypogonadism with anosmia or hyposmia (Kallmann syndrome)** • **Congenital hypogonadotropic hypogonadism with normosmia (see Table 112.2)** • **LH or LH receptor, FSH or FSH receptor gene defects**	• Pituitary or CNV tumors • Postsurgery or irradiation, trauma, vascular • Infiltrative diseases (hemochromatosis, sarcoidosis) • Lymphocytic hypophysitis • Traumatic brain injury • Drugs • Anabolic steroids • Systemic illness
Spermatogenesis Defects With Decrease in Sperm Concentration	
• **Chromosomal aneuploidy (XXY, XX males)** • **Chromosomal structural anomalies (translocation, inversion)** • **Y chromosome microdeletion (AZFa, AZFb, and AZFc; gr/gr deletion in AZFc region)** • **Chromosomal copy number variations** • **Mild partial androgen insensitivity (*AR*)** • **Monogenic X chromosome and autosome gene mutations (*TEX11, 14, 15; STAG3; SYCE1; DMRT1; MEIOB; FANCA; FAMCM; SYCP3; MEI1; MAGEA9; and many others)*** • **Cryptorchidism/testicular dysgenesis syndrome (probably genetic or epigenetic)**	• Orchitis • Drugs, toxins, irradiation • Postorchiectomy, complicated inguinal surgery (iatrogenic), trauma, testicular torsion, varicocele (grade 3)
Sperm Motility, Morphology, Function, or Genetic Incompetence	
• **Sperm flagella: primary cilia dyskinesia, multiple morphological abnormality of sperm flagella** • **Sperm head: globozoospermia, macrocephalic sperm** • **Advanced paternal age** • **Autoimmunity (probably genetic)**	• Oxidative stress • DNA damage
Ductal Obstruction or Dysfunction	
• **Congenital bilateral absence of vas deferens (mutation in *CFTR, ADGRG2*)** • **Young syndrome (probably genetic)**	• Epididymal obstruction • Vasectomy/vas occlusion • Seminal vesicle and prostate disorders • Ejaculatory duct dysfunction • Posthernia repair, pelvic surgery, retroperitoneal lymph node dissection • Severe sexual erectile or ejaculatory dysfunction (spinal cord injury, multiple sclerosis, neurotube defects)
Idiopathic	
• **Idiopathic azoospermia or oligozoospermia, athenozoospermia, and teratozoospermia (Likely genetic)**	

CFTR, Cystic fibrosis transmembrane conductance regulator; *FSH,* follicle-stimulating hormone; *LH,* luteinizing hormone.
Adapted from Çayan S, Shavakhabov S, Kadioglu A. Treatment of palpable varicocele review in infertile men: A meta-analysis to define the best technique. J Androl. 2009;30(1):33-40. Accessed 29 September 2015. https://doi.org/10.2164/jandrol.108.005967.

infundibulitis may spontaneously involute or require pharmacological treatment of the inflammation and may cause hypogonadotropic hypogonadism.[25] Recent studies showed that cancer immunotherapy with checkpoint inhibitors may induce hypophysitis resulting in adrenal, thyroid, and gonadal insufficiency. Recovery from central hypogonadism from checkpoint inhibitors is common when compared to adrenal or thyroid insufficiency.[26]

Vascular Lesions. Vascular lesions include pituitary infarction and carotid aneurysm. Sheehan syndrome is an example of the former.

Traumatic Brain Injury. Anterior pituitary dysfunction occurs in the early posttraumatic brain injury period and may persist after the acute period. The frequency of pituitary dysfunction depends on the severity and type of trauma. Though hypogonadism may be transient, surveillance is required to ensure the patient does not develop persistent hypogonadotropic hypogonadism.[27]

Endocrinopathies. Suppression of the hypothalamus-pituitary axis may be caused by other endocrinopathies. While any cause of hyperprolactinemia (drugs, hypothyroidism) may be incriminated, prolactinoma is the most common cause of hypogonadotropic hypogonadism in men. Chronic supraphysiological glucocorticoid secretion and other causes of Cushing syndrome in men may result in low serum testosterone concentrations and inappropriately normal serum gonadotropins, due to suppression of hypothalamic GnRH secretion as well as suppressed testicular androgen synthesis.

Androgens and Other Sex Steroids. Administration of exogenous testosterone, other anabolic steroids, as well as estrogens and progestins suppress both LH and FSH secretion and serum concentrations and result in oligo- or azoospermia. Anabolic steroid use should be suspected in men with low sperm concentration, low serum LH concentrations,

TABLE 112.2 **Most Frequently Reported Genes Associated With Congenital Hypogonadotropic Hypogonadism**

Gene	Gene Product/Function	Clinical Features
Genes Associated With GnRH Neurons Development or Migration (Kallmann Syndrome)		
***ANOS1* (formerly *KAL1*)**	Anosmin 1 (X-linked)	Anosmia or hyposmia, unilateral renal agenesis, midline facial defects, synkinesia (cerebellar abnormality)
***FGFR1* (formerly *KAL2*)**	Fibroblast growth factor receptor 1 (autosomal dominant, digenic)	Anosmia to normosmia, cleft palate/lip, synkinesia, syndactyly and other skeletal abnormalities, dental agenesis
FGF8	Fibroblast growth factor 8 (autosomal dominant or recessive)	Anosmia to normosmia, cleft palate/lip
PROK2	Prokineticin 2	Anosmia to normosmia
PROKR2	Prokineticin receptor 2 (autosomal dominant or recessive)	
CHD7	Chromodomain helicase DNA-binding protein 7 (autosomal dominant)	Mild phenotype of CHARGE syndrome (eye coloboma, heart defects, choanal atresia, retarded growth, genital hypoplasia, ear anomalies, and deafness), anosmia to normosmia
Others: *NELF* (nasal embryonic LHRH factor), *WDR11* (WD repeat containing protein), and many others		
Genes Associated With GnRH Secretion and Action		
KISS	Kisspeptin	Central precocious puberty, no infertility
KISSR	KISS receptor, autosomal recessive	Normosmia
LEP	Autosomal recessive	Severe obesity
LEPR	Leptin	Severe obesity
	Leptin receptor	
TAC3	Neurokinin B	Cryptorchidism, microphallus
TAC3R	TAC3 receptor (autosomal dominant of recessive)	
GnRH1	GnRH (autosomal recessive)	No smell or midline defect
GnRHR	GnRH receptor (autosomal recessive or digenic) inheritance	
Others: *PCSK1* (protein convertase subtilisin/kexin-type 1); *NROB1* (dosage sensitive sex reversal adrenal hypoplasia congenital *DAX1*), and many others		

Adapted from Krausz C, Rosta V, Swerdloff RS, Wang C. Genetics of male infertility. In: Pyertitz R, Korf B, Grody W, eds. *Emery and Rimoin's Principles and Practice of Medical Genetics and Genomics.* 7th ed. Elsevier; 2021:in press.[10]

but with a well-androgenized phenotype.[28,29] A recent observational study of current and past androgen abuser showed that recovery of LH occurs faster than FSH, spermatogenesis, and sperm output and the slower recovery is related longer duration of drug abuse.[30,31] Healthy men who were administered androgen together with progestins in male contraceptive studies also demonstrate marked suppression of sperm output, which is reversible after discontinuation of treatment; the time to recovery is influenced by the type and duration of androgen administration[32] (see Chapter 115). In a review of 1540 men evaluated for infertility, 110 (7.1%) were on supplemental testosterone. Median sperm concentration 4.5 months after stopping testosterone increased from 0 to 6.3 million/mL, but some men remained azoospermic for more protracted periods indicating a longer follow-up period may be required.[33]

Other Drugs. Many drugs can affect male fertility including those acting on the hypothalamic-pituitary-gonadal axis (see Chapter 113; Table 113.2). Thus assessment of a man with infertility must include detailed drug history.[34] Chronic use of pharmacologic doses of glucocorticoids may lead to decreased intratesticular testosterone concentration, inhibition of spermatogenesis, and male infertility. Opioid-like or other central nervous system–activating drugs, including many psychotropic drugs, can inhibit GnRH or gonadotropin secretion, resulting in secondary hypogonadism and infertility.[35] Administration of GnRH analogs (agonists and antagonists) to suppress gonadotropin secretion in men with prostatic carcinoma results in hypogonadism and infertility.[36]

Systemic Illness. Any serious systemic illness or chronic nutritional deficiency can cause hypogonadotropic hypogonadism, primary hypogonadism, and infertility.

KEY POINTS

- Hypothalamic-pituitary endocrine disorders (with low serum testosterone) represent a small percentage of overall cases of male infertility.
- Congenital hypogonadotropic hypogonadism can be due to defects in the development and migration of the GnRH neurons (Kallmann syndrome associated with anosmia and other developmental defects) or in impaired GnRH secretion or action (GnRH receptor defects) not associated with olfactory anomalies. Congenital hypogonadotropic hypogonadism undergoes spontaneous remission in 10% to 20% of patients (both adolescents and adults).
- Other genetic defects such as gonadotropins and gonadotropin receptors are very rare.
- More commonly acquired hypothalamic-pituitary disorders are sellar and suprasellar lesions: pituitary adenomas, craniopharyngiomas, meningiomas, lymphocytic hypophysitis, Rathke's cleft cysts, germinomas, and drugs (opioids and androgenic steroids) and severe systemic illness.
- Since specific therapies are available, it is important to diagnose these disorders.

Testicular Disorders With Spermatogenesis Defects

About 75% of infertile men have primary testicular impairment; including 20% due to known genetic causes and 30% to 40% acquired disorders and 40% to 50% "idiopathic."[8,10] This group of disorders affect spermatogenesis leading to decreased or absent production of spermatozoa and oligozoo- or azoospermia.[9] Current recommendations suggest that men with severe oligozoospermia (sperm concentration <5 million/mL ejaculate) and nonobstructive azoospermia should have genetic screening studies performed.[37] In selected cases based on the phenotype, monogenic defects can be screened.[10,38]

Congenital Spermatogenesis Defects

Chromosomal Defects. About 13.7% of azoospermic and 4.6% of oligozoospermic males have sex chromosomal disorders. Azoospermia or severe oligozoospermia (<5 million spermatozoa/mL ejaculate) is associated with sex chromosome abnormality and Y chromosome microdeletions,[39] whereas less severe oligozoospermia (>5 million spermatozoa/mL ejaculate) with autosome anomalies such as Robertsonian and reciprocal translocations or inversions.[40]

Klinefelter Syndrome, XYY and XX Males. The most common chromosomal disorder associated with male infertility is Klinefelter syndrome (KS) occurring in 1:600 males.[41] The karyotype is usually 47, XXY but mosaicism (46,XY/47,XXY) does occur. Addition of another X chromosome to XXY causes a more severely affected phenotype. Infertility, bilateral small, firm testes, and azoospermia occurred in 99% of men with 47,XXY karyotype. They are tall and usually hypogonadal with decreased body hair, gynecomastia, eunuchoid proportions, and decreased muscle mass and strength and abdominal obesity (in 60% to 80% of KS men).[41,42] In addition, they have higher incidence of learning disability, delayed speech development in childhood and metabolic syndrome, type 2 diabetes mellitus, osteopenia, and autoimmune diseases in adulthood.[43] Men with untreated KS usually have elevated FSH, LH, and low or borderline low testosterone concentrations. The testis in adult KS men showed hyalinization of the seminiferous tubules and hyperplasia of the Leydig cells. However, about 50% of patients with KS have pocket of spermatozoa in the seminiferous tubules that is even higher (70%) in adolescents 12 to 20 years old (see Chapter 113). The current treatment for these patients with azoospermia who desire fertility is to harvest spermatozoa using microsurgical testicular sperm extraction (TESE) followed by intracytoplasmic sperm injection (ICSI) (see Chapter 113). Though not currently the standard of care, early fertility preservation with sperm and testicular tissue cryopreservation in adolescent boys with KS are under investigation.[44]

Other sex chromosome anomalies include XYY males and XX males. XYY men have normal-to-severe spermatogenesis defect. In most of the XX males, there is a translocation of the *SRY* gene (sex-determining gene, located right below the pseudoautosomal region of the Y chromosome) to the X chromosome. Though the genotype is XX, due to the presence of the SRY gene, the phenotype will result in a male but with spermatogenic failure. XX males are not tall, does not have eunuchoid proportions, and have no spermatozoa in the testis because of the absence of spermatogenesis genes mapping to the long arm of the Y chromosome.[10]

Structural Chromosomal Aberrations. Robertsonian translocation, reciprocal translocations, and inversions are most frequently found in oligozoospermic men. Reciprocal translocations occur with breaks in each of two nonhomologous chromosomes that exchange the broken segments. Robertsonian translocation involving chromosomes 13, 14, 15, 21, and 22 occurs in 1 in 1000 live births with the fusion of two acrocentric chromosomes, where the long arms are fused and the short arms are lost resulting in 45 chromosomes. The balanced form usually has no health problems. In unbalanced translocations, monosomy or trisomy are associated with phenotypes including trisomy 21.[45] In a large cohort, 95% of adults with balanced Robertsonian translocations have infertility, miscarriage, or offspring with chromosomal abnormalities.[46] In another study, balanced reciprocal translocations are associated also with infertility.[47] It is important to detect these structural chromosomal anomalies because of increased risk of aneuploidy and unbalanced translocations in the offspring that may lead to Angelman or Prader-Willi syndromes. New molecular and sequencing techniques can now correctly diagnose chromosomal rearrangements in the parents and in the embryo.[48,49]

Y Chromosome Microdeletions. The Y chromosome is an acrocentric chromosome with pseudoautosomal regions that are homologous with the X chromosome sequences and the male-specific Y region that is critical for spermatogenesis. This chromosome has many segmental duplications, direct or inverted repeats, including palindromes allowing for recurrent deletions/duplications controlling the dosage of different Y genes. The AZF (azoospermia factor) region has recurrent microdeletions in three subregions in the proximal, middle, and distal Yq11 named AZFa, AZFb, and AZFc. AZFa region contains *USP9Y* and *DDX3Y genes* and deletions of AZFa result in Sertoli cell–only syndrome. Males with AZFa deletions are infertile without germ cells in the testis. Complete AZFb deletions result in spermatogenic arrest, absence of mature germ cells, and male infertility. In contrast, deletions of the AZFc region may present in men with oligozoospermia to azoospermia. Azoospermia may be due to progressive loss of germinal epithelium with time or the consequence of 46,XY/45,XO mosaicism or environmental influences. Y chromosome deletions occur in about 5% to 7.5% of infertile men and the highest incidence is found in azoospermic men. AZF microdeletion testing is standardized and generally requested for men with severe oligozoospermia <5 million/mL, not only for diagnosis but in case of azoospermia it is also relevant for predicting whether TESE is a viable option.[50,51] For men who will undergo TESE and ICSI, genetic counseling is necessary as the son will carry the Y microdeletion and will be affected by impaired sperm production.[10]

Partial deletion and duplication of the AZFc region, gr/gr deletion, is a significant risk factor associated with male subfertility in some populations such as East Asian and White American men but not in Black and some European men.[51–54] The risk of spermatogenesis defects is increased by 2- to 2.5-fold in men with gr/gr deletions and is highest in men of Mediterranean origin. Testing for this deletion in infertile men should be offered for the couple because this deletion is transmitted to the male progeny and is associated with a risk of developing testicular germ cell tumors (TGCTs). In multicenter studies, gr/gr deletions increased the risk of TGCTs especially in normospermic men by 3.7-fold.[55]

Copy Number Variations. These chromosome variations involve gains and losses of homologous sequences in chromosomal segments. Men with spermatogenesis defects have higher load of copy number variations.[56–58] If this occurs in the single X chromosome in the male that may lead directly to a deleterious effect in the absence of a compensatory normal allele. X-linked deletion, CNV67, leads to deletion of the proximal copy of the testis-specific *MAGEA9* (*melanoma antigen family A,9B*) gene specifically expressed in spermatogonia.[59] The associated semen phenotype ranges from azoospermia to oligozoospermia. The intragenic deletion of the X-linked *TEX11* (*testis-expressed 11*), a gene required for male germ cell meiosis, leads to azoospermia due to meiotic arrest.[60]

Mild Partial Androgen Receptor Insensitivity. Androgens are essential for postmeiotic development of spermatocyte, spermatids to spermatozoa, and for the release of spermatozoa from the germinal epithelium to the lumen. Mutations of the androgen receptor gene are uncommon and result in variable phenotype from a phenotypic female in complete androgen insensitivity syndrome, undervirilized male with ambiguous genitalia in partial androgen insensitivity to a normal male with infertility, and defective spermatogenesis (see Chapter 105).[61] Patients with complete or partial androgen insensitivity syndrome are infertile. Mutations in the transactivation or the ligand-binding domain of the androgen receptor may result in defective spermatogenesis.[62]

The transactivation domain of the androgen receptor contains two segments of glutamine (CAG) and glycine (GCN) repeats. Expansion of the CAG repeats (>39 CAG) in exon 1 of the transactivation domain of the androgen receptor leads to Kennedy syndrome, spinal bulbar atrophy, that is associated with progressive hypogonadism and testicular atrophy. The relationship between CAG or GCN repeats with male infertility is controversial. Meta-analyses show that such association may be present in Asians but not in White Europeans and thus expansion of CAG repeats (in the polymorphic range, i.e., <39 CAG) may only play a minor role in male infertility in some populations but not others.[62–64]

Monogenic and Autosomal Mutation. The advent of next-generation sequencing and whole-exome sequencing allows the identification of many novel spermatogenesis-related gene defects in men with nonobstructive azoospermia or oligozoospermia (Table 112.1).[65–68] The large majority of gene defects are recessive and often are found in consanguineous families. The most frequently reported monogenic defect of meiotic arrest is due to *TEX11* mutations. The clinical importance of diagnosing these genetic factors is not only for identifying the monogenic defects but also because some of these defects are consistently associated with Sertoli cell–only syndrome or maturation arrest with prognostic and treatment implications. A future nonobstructive azoospermia gene panel based on genes with strong/definitive clinical evidence would avoid unnecessary surgical sperm extraction.[69]

Recessive mutations in the Fanconi's anemia gene pathway (*FANCA*) have been identified in infertile men with Sertoli cell–only syndrome and mild hematological abnormalities. This finding implies that the two different compartments, germinal epithelium and bone marrow, may share common genetic defects involved in DNA damage repair. Late-onset Fanconi's anemia can be diagnosed during genetic investigations for male infertility.[70] Mutations in other genes involved in DNA damage repair (FANCM) have also been reported in infertile men implying that carriers of these genetic defects may be predisposed to cancer.[67]

Cryptorchidism. Cryptorchidism affects 2% to 9% of full-term newborn boys. Testicular descent is regulated by testosterone and insulin-like 3 (INSL3), both are products of Leydig cells. Cryptorchidism associated with hypospadias and testis cancer may originate *in utero* and are components of the "testicular dysgenesis syndrome." *In utero* environmental exposure to antiandrogens such as phthalates and estrogens like dioxin have been suggested to be the cause of the increasing prevalence of cryptorchidism (and other reproductive defects) in some but not all regions (discussed later in the chapter).[71] Men with a history of undescended testes have lower sperm counts, poor sperm quality, and lower fertility rates than men with normally descended testes. Impaired spermatogenesis in the undescended testis is probably related to underlying genetic, hormonal, and developmental abnormalities, some of which may be partially reversible through early surgical intervention. The degree of germ cell dysfunction with cryptorchidism is correlated with the duration of suprascrotal location of the testes. Early surgical correction of cryptorchidism may improve fertility but not the risk of testicular cancer.[72] TGCTs are associated with cryptorchidism and impaired spermatogenesis.[73] TGCT occurs mainly in adolescent and young adults due to impaired gonadal development, arrest of prespermatogonia differentiation, and retention of embryonic pluripotent features associated with genomic instability. Cryptorchidism in Klinefelter and Kallmann syndrome is related to decreased production of testosterone and INSL3 by the Leydig cells. Though INSL3 and its receptor are important in the descent of the testis, no mutations of these genes have been reported. Apart from the above-mentioned syndromic forms, in the majority of cases the pathophysiology of cryptorchidism is unknown. Genome-wide association studies identified gene polymorphisms associated with cryptorchidism, yet no single-gene defect has been identified.[74]

KEY POINTS

- Genetic studies are recommended for infertile men with nonobstructive azoospermia and severe oligozoospermia (<5 million spermatozoa/mL ejaculate).
- Klinefelter syndrome is the commonest chromosomal abnormality in males and is associated with azoospermia and hypogonadism in the majority of patients.
- Robertsonian and reciprocal translocations are more frequent in infertile men with oligozoospermia and the diagnosis is important as these rearrangements may become unbalanced in the offspring.
- Y chromosome microdeletions are the most common molecular genetic causes of spermatogenic impairment. Genetic counseling is important as this genetic defect is transmitted to the male progeny.
- Monogenic spermatogenesis gene defects are increasingly being identified using next-generation sequencing and are mostly recessive.
- Genetic defects can be transmitted through assisted reproductive techniques to the future offspring. Preintervention/conception counseling and genetic testing should be considered.
- Cryptorchidism is the commonest male reproductive developmental defect, but the exact pathophysiology is yet to be discovered, probably involving genetic susceptibility, hormonal, and other factors during development.

Syndromic Monogenic Defects. The genetic defects associated with these syndromes may disrupt single-gene function, may lead to the inactivation of imprinted genes, or are related to expansion of trinucleotide repeats.

Bardet-Biedl Syndrome. Patients with Bardet-Biedl syndrome present with obesity, polydactyly, mental retardation, renal anomalies, hypogonadism with cryptorchidism, hypospadias, and micropenis. This syndrome is associated with mutations of *BBS*.

Prader-Willi Syndrome. This syndrome is associated with hypotonia, developmental delay, mental retardation, and obesity. Prader-Willi syndrome is associated with the absence of genes in the imprinted region of paternal chromosome 15q11-q13 in 70% of cases; the remainder is associated with maternal gene disomy or defective imprinting.

Noonan Syndrome. Patients with Noonan syndrome have short stature, heart failure due to cardiomyopathy or pulmonary valve lesions, dysmorphic facial features, and cryptorchidism in boys. The most common gene mutation is in *PTPN11* that encodes the nonreceptor protein phosphate SHP-2.

Myotonic Dystrophy. Myotonic dystrophy is caused by an expansion of the trinucleotide CTG repeats at chromosome 10p13.3. Genes with 50 to 80 repeats are unstable and may expand more in transmission to the offspring. The clinical severity of the disease is related to the number of repeats. Muscle dystrophy is associated with cardiac conductance problems, cataracts, progressive testicular atrophy, infertility, and hypogonadism.

Acquired Spermatogenesis Defects. This section will discuss infections, drugs, toxins, irradiation, and trauma to the testis and presence of varicocele on male infertility.

Infection. Viral orchitis, especially mumps, is a well-recognized cause of infertility. Among those with mumps, unilateral clinical orchitis is rare in prepubertal males but occurs in about 10% to 20% of adult men. The virus can directly affect Leydig and germ cells or through an indirect immune mechanism. Orchitis is frequently accompanied by epididymitis. Prior vaccination against mumps virus decreases the severity of the disease. Outbreaks of mumps orchitis occur that may be due to incomplete vaccination or waning immunity.[75] The affected testis may become atrophic in about half of the cases and is associated with oligozoospermia and infertility. In mumps and other viral causes of orchitis (echovirus and arbovirus), germ cell failure is much more common than androgen deficiency.[76]

Other infectious causes of orchitis and infertility include tuberculosis and leprosy; the former may also cause epididymal obstruction. Sexually transmitted infections (STIs) such as gonorrhea, chlamydia, ureaplasma, herpesviruses (HSV), human papillomaviruses (HPV), hepatitis B and C viruses, human cytomegalic virus (HCMV), and human immunodeficiency virus (HIV) are detected in symptomatic as well as asymptomatic men with testis, accessory gland, and urethral infections. These bacteria, viruses, and protozoa are associated with decreased semen quality, including lower concentration and motility, and may cause male infertility. White blood cells may be present in the semen, especially if HIV was associated with other STIs such as gonorrhea. Very sensitive molecular methods are now available to allow investigation of the relationship between STD infections and male infertility. Chronic inadequate STI treatment may result in more damage and infertility than acute infections.[77–80] All the pathogens present in the semen can be transmitted to the partners and newborns, and screening for HIV, HPV, HSV, and HCMV in male patients is advised to prevent viral transmission and adverse outcome of fertility.[80,81]

Drugs and Radiation. Chemotherapy: Many drugs are associated with impaired spermatogenesis and/or Leydig cell dysfunction. Among them, the most important are alkylating drugs used in chemotherapy of hematological malignancies in children and adults. Childhood cancer has a survival rate of over 85%. The Childhood Cancer Survivor study showed that males have reduced likelihood of siring a pregnancy. This reduction in fertility is related to the dose of alkylating agents (cyclophosphamide, ifosfamide) or DNA interstrand crosslinking drugs (procarbazine and cisplatin).[82] Fertility preservation is recommended for boys and young adults undergoing chemotherapy.[83–85] Semen cryopreservation should be performed before chemotherapy for those that can produce a sample. For those where semen samples cannot be obtained, testicular biopsy and cryopreservation of testicular tissue for future *in vitro/in vivo* germ cell development are available in some centers.[86,87]

Ionizing radiation: Irradiation of the scrotal area impairs spermatogenesis but not Leydig cell function until very high dose >30 Gy is administered. Doses as low as 0.5 Gy may transiently suppress spermatogenesis, whereas doses above 3 Gy (600 rad) usually cause prolonged azoospermia and infertility. Doses over 16 to 18 Gy result in permanent azoospermia.[88]

Antiandrogens: Flutamide, cyproterone, bicalutamide, spironolactone, ketoconazole, and cimetidine impair spermatogenesis by disrupting the hypothalamic-pituitary-testis (HPT) axis altering androgen action (see Chapter 113, Table 113.2).

Testicular Torsion and Trauma. Testicular torsion and injury lead to ischemia and rapid loss of germ cells. In addition, ischemia followed by reperfusion triggers the generation of reactive oxygen species, proinflammatory cytokines, anoxia, and apoptosis with a high risk of subsequent infertility.[89] Emergent surgical intervention in emergency with unilateral orchiopexy and orchiectomy may reduce future subfertility.[90]

Varicocele. Varicoceles are dilatations of the pampiniform plexus of the spermatic veins in the scrotum. Left-sided varicoceles are 10 times more common than right-sided ones, perhaps because of the almost 90-degree angle with which the left spermatic vein enters into the renal vein causing a lower blood efflux. Varicoceles are found in about 10% to 15% of normal men while this percentage is higher in infertile men. In a large study of over 9000 infertile couples, the presence of a varicocele was accompanied by decreased testis volume and impaired semen parameters that may contribute to spermatogenesis defects.[91] The mechanisms by which varicocele causes infertility and the reversibility of infertility after varicocele surgery are controversial. Increased oxidative stress may be one of the mechanisms. Current evidence suggests that varicocelectomy may have a beneficial effect on semen quality and pregnancy outcomes only if the male has a clinically palpable varicocele (grade 3) and abnormal semen parameters.[92,93]

Sperm Motility, Morphology, Function, or Genetic Incompetence—Spermatogenesis Qualitative Defects

Congenital Qualitative Sperm Defects

Sperm Flagellum Defects. Primary cilia dyskinesia (immotile cilia syndrome) is characterized by abnormal ciliary motion and mucociliary clearance in the bronchus, sinuses, and nose. Males are infertile because of poor sperm motility due to defective function of the flagella. This defect is associated with chronic respiratory disease and situs inversus in about half of the patients (Kartagener syndrome). There are over 40 genes related to ciliary dyskinesia. Recessive mutations of the genes *DNAH5* and *DNAH11* result in the absence of the dynein arms in the cilia and the flagellum of spermatozoa resulting in impaired movement and function and male infertility.[94]

Multiple Morphological Abnormalities of the Sperm Flagella. Patients with multiple morphological abnormalities of the sperm flagella (MMAF) have multiple abnormalities of the sperm flagella (absent, coiled, bent, angulated, irregular). MMAF is one of the most severe forms of sperm flagellum defects that are not associated with recurrent respiratory infections. Because in the human sperm flagella several hundreds of proteins are involved, many gene defects have been identified in MMAF. These include *DNAH1, CFAP43, CFAP44, CFAP69, SPEF2*, and many others that affect axonemal or periaxonemal protein complexes. However, patients with *DNAH1* have good outcomes following ICSI.[95–97]

Sperm Head Defects. Sperm head defects that result in severe teratozoospermia have genetic bases. An example is the identification of new genes using whole-exome sequencing for human globozoospermia (sperm with round heads and acrosome defects). Mutations of *DPY19L2* are responsible for 70% of all cases of globozoospermia; using exome sequencing six other new genes have been identified.[98] Another sperm head morphological abnormality is macrozoospermia (macrocephalic sperm heads) that is associated with mutations of *AURKC* in up to 80% of patients. These sperm head defects are usually not compatible with normal embryo development due to tetraploidy of the spermatozoa.[99]

Advanced Paternal Age. As men age, sperm concentration does not usually decrease but semen volume, sperm motility, and spermatozoa with normal morphology decrease[100] and sperm DNA fragmentation[101] increases. DNA damage in the spermatozoa with advanced paternal age may affect the pregnancy outcome, whereas epigenetic changes are predicted to affect health of the offspring. Some dominant diseases, such as Apert, Noonan, Costello, Crouzon, Pfeiffer syndromes, achondroplasia, and multiple endocrine neoplasia (types 2A and 2B) present a higher frequency in children born to older fathers. These genetic diseases are considered as paternal age effect diseases.[102,103] In addition, mental disorders such as autism, schizophrenia, bipolar disorder, low IQ, as well as attention deficit hyperactivity disorder occur more frequently in offspring from fathers of advanced age.[104]

Sperm Autoimmunity. The presence of sperm agglutination in the semen should trigger the laboratory to test for antisperm antibodies. Whether antibodies occur spontaneously or only after testicular injury or infection is not known. About 2% to 4% of infertile men have antisperm antibodies in serum or semen and both presumably could impair spermatogenesis.[105] Men with antisperm antibodies have lower sperm concentration (but not oligozoospermia) and sperm progressive motility.[106] A multicenter case-control study found that infertile men with normozoospermia and positive sperm antibodies have more acrosome reaction and hyperactivation disorders, oxidative stress, and DNA fragmentation than fertile men suggesting that sperm autoimmunity may impair sperm function.[107] However, the exact role of sperm antisperm antibodies in male infertility remains controversial. Experimental models have demonstrated that infection and inflammation of the testis may result in autoimmune orchitis. Patients with autoimmune polyendocrinopathy and those with systemic autoimmune disease may have autoimmune testicular disease but there are many other unknown factors.[108]

Acquired Sperm Qualitative Defects. Infection and inflammation of the genital system may increase the production of reactive oxidative species by leucocytes impairing the functional competence of spermatozoa. Oxidative stress results in DNA damage that may affect *in vitro* fertilization success rate but the effects on the health of the offspring are not well established.[109]

KEY POINTS: Sperm Qualitative Defects (sperm motility, morphology, function or genetic incompetence)

- Genetic analysis of large consanguineous families and the recent use of whole exome sequencing allowed the identification of genetic mutations causing flagellum defects in ciliary dyskinesia and multiple morphological abnormality of sperm flagella and gross sperm head morphological defects including globozoospermia and macrozoospermia.
- Advanced paternal age affects sperm motility and DNA integrity. Moreover, spermatozoa of aged men carry dominant mutations more frequently causing the so-called Paternal Age Effect diseases such as Apert syndrome, achondroplasia and multiple endocrine neoplasia (Type 2 A and B), as well as mental disorders.
- Sperm autoantibodies are detected in about 2 to 4% of infertile men and their effect on male fertility is not clear.
- Acquired sperm function defects with oxidative stress and DNA damage may be associated with inflammation and infection of the genital tract.

Ductal Obstruction or Dysfunction

Infertile men with ductal obstruction have normal reproductive and endocrine function. Physical examination with imaging is useful in the diagnosis of the site of the obstruction in the urogenital tract.

KEY POINTS: Ductal Obstruction

- Congenital Bilateral Absence of Vas Deferens is the commonest genetic cause of ductal obstruction mainly due to mutations of the *CFTR* gene. Small proportion of these patients may have mutations of the X-linked *ADGRG2* gene or associated with unilateral renal agenesis where the underlying mechanisms have yet to be identified.
- Obstructive azoospermia with chronic sinusitis-pulmonary infections called Young's syndrome is a rare disease and the genetic cause has not been defined.
- Epididymal obstruction usually due to prior infection is the most common cause of acquired proximal obstruction followed by vasectomy or vas occlusion procedures. Midline prostatic cyst and ejaculatory duct obstruction are correctable by minimally invasive aspiration of the cyst or surgery.
- Severe erectile and ejaculatory dysfunction related to neurological diseases, spinal cord injury or systemic disorders such as diabetes mellitus must be recognized and treated.
- Men with congenital bilateral obstruction of the vas deferens must be counseled and tested for the CFTR gene before epididymis sperm extraction and ICSI.

:Genetic Causes of Ductal Obstruction

Congenital Bilateral Obstruction of the Vas Deferens. Congenital bilateral absence of the vas deferens (CBAVD) is the cause of about 1% to 2% of male infertility and up to 6% of obstructive azoospermia.[8] Men affected by cystic fibrosis have CBAVD. Mutations of the gene encoding cystic fibrosis transmembrane conductance regulator (*CFTR*) can lead to CBAVD as a monosymptomatic, mild form (male infertility) of cystic fibrosis. Some *CFTR* variants are more frequently found in CBAVD. CBAVD without other symptoms of cystic fibrosis are due to the combination of either two mild mutations or one mild mutation and one severe mutation. The polymorphic poly-T tract in intron 8 may influence the severity of the phenotype and IVS8-5T is considered a mild mutation. CBAVD men can sire a progeny by either epididymal or TESE followed by ICSI. Genetic counseling and testing are essential to prevent the couple having a child with cystic fibrosis. The female partner of a patient affected by CF or CBAVD must be screened for *CFTR* mutations since in some populations the carrier frequency of *CFTR* mutations can be as high as 1:25. Depending on the genotype of each partner, the option for preimplantation genetic diagnosis should be discussed with the couple before assisted reproductive techniques are used.[110] About 20% of CBAVD men who are negative for *CFTR* mutations are hemizygous for a mutation of the X-linked *ADGRG2* gene. Some men with this obstructive disorder present with unilateral kidney agenesis suggesting early organogenesis disorder that is independent from CFTR.[111] The underlying mechanisms of this pathological condition are still unknown.

Young Syndrome. Men with Young syndrome present with obstructive azoospermia and chronic sinopulmonary infections.[112] The obstruction in the bronchi and epididymides is due to inspissated secretions. This disease is very rare and has been related to mercury exposure in childhood.[113] Presumably genetic in origin, but no specific genes have been identified.

Acquired Ductal Obstruction

Abnormalities of the Epididymis. Absence, dysfunction, infection,[108] or obstruction of the epididymis leads to infertility even though testicular sperm production may be normal. Intrauterine exposure to estrogens may cause epididymal dysfunction. While poorly documented, it is presumed that some men with isolated asthenozoospermia (impaired motility) have defects of epididymal function.[114]

Abnormalities of the Vas Deferens. Bilateral obstruction, ligation, or altered peristalsis of the vas deferens results in infertility. Obstruction may result from infection (gonorrhea, chlamydia, tuberculosis), whereas ligation of the vas deferens (vasectomy) is an intentional, medically induced cause of infertility (male contraception). Though the patency of the vas can be restored by vasovasostomy of vasoepididymostomy, the pregnancy rate in the female partner is much lower.[115]

Seminal Vesicles and Prostate. Congenital absence of the seminal vesicles is associated with CBAVD. The prostate gland secretes zinc, citrate, and kallikreins that may be important for sperm function. Inflammation of the prostate or seminal vesicles may be associated with abnormal sperm parameters and function.[116] Midline prostatic cysts were present in 10.2% male partners of infertile couples compared to 5.8% fertile men. Men with larger midline prostatic cyst had low sperm concentration. Transrectal ultrasound-guided cyst aspiration may improve sperm concentration.[117]

Ejaculatory Duct Obstruction. Patients with ejaculatory duct obstruction present with a low ejaculate volume and no sperm and/or very low sperm motility. Ejaculatory duct obstruction is found in up to 5% of infertile men and can be diagnosed and treated surgically with minimally invasive techniques (transurethral resection of the ejaculatory ducts).[118]

Postsurgery. Prior inguinal hernia repair may inadvertently injure leading to scarring of the vas deferens affecting sperm transport. Retroperitoneal lymph node dissection and posterior pelvic surgery may damage the sympathetic supply to the vasa, seminal vesicles, and bladder neck resulting in interruption of sperm transport.

Severe Sexual and Ejaculatory Dysfunction. Erectile dysfunction, mechanical obstruction (condoms and diaphragm use), premature ejaculation, and ejaculatory failure may cause male infertility in about 4% of infertile men.[8] Neurological disease including multiple sclerosis, transverse myelitis, and defects of the neural tube interferes with normal ejaculation. Long-standing diabetes mellitus with autonomic neuropathy may result in retrograde ejaculation and severe erectile and ejaculatory dysfunction.[8,9] These causes should be determined by careful history, examination, and diagnostic workup.

KEY POINTS

- Congenital bilateral absence of vas deferens is the commonest genetic cause of ductal obstruction mainly due to mutations of the *CFTR* gene. Small proportion of these patients may have mutations of the X-linked *ADGRG2* gene or associated with unilateral renal agenesis where the underlying mechanisms have yet to be identified.
- Obstructive azoospermia with chronic sinusitis-pulmonary infections called Young syndrome is a rare disease and the genetic cause has not been defined.
- Epididymal obstruction usually due to prior infection is the most common cause of acquired proximal obstruction followed by vasectomy or vas occlusion procedures. Midline prostatic cyst and ejaculatory duct obstruction are correctable by minimally invasive aspiration of the cyst or surgery.
- Severe erectile and ejaculatory dysfunction related to neurological diseases, spinal cord injury, or systemic disorders such as diabetes mellitus must be recognized and treated.
- Men with congenital bilateral obstruction of the vas deferens must be counseled and tested for the CFTR gene before epididymis sperm extraction and ICSI.

Idiopathic Azoospermia, Oligozoospermia, Asthenozoospermia, and Teratozoospermia

Despite the advances in the management of male infertility using assisted reproductive technologies, the cause of male infertility remains not yet identifiable in about 40% of infertile men. As there are over 1500 genes that are involved in human spermatogenesis, only a small proportion have been identified causing quantitative and qualitative spermatogenesis defects. In the most severe forms of infertility, we expect to identify new single-gene mutations affecting spermatogenesis that are sporadic. Environmental factors may cause infertility through interaction with individual genetic background or by inducing epigenetic modifications. The challenge in male infertility is to identify the causes of idiopathic infertility, find specific treatment to correct the problem, and prevent the recurrence of the problems in susceptible individuals.[9,10,119]

OTHER POSSIBLE CONTRIBUTING FACTORS TO MALE INFERTILIY

Obesity

Obesity is a pandemic that is affecting all regions of the world. It is associated with increased risk of cardiovascular disease, type 2 diabetes mellitus, and reproductive disorders including hypogonadism and male infertility. Obesity in men may result in suppression of the HPT axis with low total testosterone, free testosterone, and low or inappropriately normal gonadotropin concentrations. The obesity-associated decrease in serum sex hormone–binding globulin (SHBG) contributes to the low serum total testosterone concentrations.[120] In addition, free testosterone concentrations in the blood appear to be inversely related to body weight and body mass index (BMI), independent of changes in SHBG. Other factors contributing to the hypogonadotropic hypogonadism associated with obesity include an increase in estrogens through aromatization in adipose tissue, increased inflammatory cytokines[121] resulting in insulin resistance, metabolic syndrome, diabetes mellitus, and sleep apnea.

More recent studies suggest paternal obesity may affect sperm epigenomics, which can be transmitted and affect offspring reproductive function by epigenetic reprogramming of spermatogonial stem cells.[122,123] A meta-analysis of 21 studies showed that underweight, overweight, and obese men have higher risk of oligozoospermia and azoospermia.[124,125] The relationship between obesity and semen parameters is still unclear, with some studies reporting lower sperm concentrations/motility and semen volume with increasing BMI[126,127] and others finding no association or only with morbid obesity.[120,128] Both lifestyle changes, medical weight loss and bariatric surgery, demonstrate increase in testosterone but the effect on sperm concentration and infertility needs further controlled studies.[129,130] Moreover, metabolically fit versus unfit obese individual does not differ in semen parameters but evidence suggests that metabolically unfit obese men have higher cardiovascular disease risks.[131] Although these data are conflicting, advice on lifestyle changes and weight loss should be provided to obese men seeking infertility treatment, given the known negative effects of obesity on serum SHBG and testosterone concentrations. Weight loss and bariatric surgery normalize the hypothalamus-pituitary axis and increase testosterone levels and may increase sperm output, but the effect on improving fertility is controversial.[129,132,133] Thus obesity is generally considered a contributing rather than a causal factor for male infertility.[8]

Environmental Factors: Endocrine Disruptors

Testicular Dysgenesis Syndrome and Semen Quality. Although controversial, environmental factors including exposure to endocrine disruptors (antiandrogens or estrogenic compounds) *in utero* have been linked to cryptorchidism, hypospadias, poor semen quality, male infertility, and testicular cancer, the so-called "testicular dysgenesis syndrome"[71,134] (see Chapter 115). These environmental factors including pesticides (organochlorides), fungicides (vinclozolin), byproducts of solvents (dioxin and polychlorinated biphenyls), and plasticizers (phthalates, bisphenol A) affect the fetal testis, but some may also affect the adult testis. Environmental factors most probably act directly on spermatogenesis or via epigenetic modification of spermatogenesis. The transgeneration transmission of these epimutations may result in reproductive and health problems in the progeny.[71,135–138] Environmental exposure may also be the cause of variation of semen parameters across regions where men from agriculture intensive area have higher concentrations of pesticides and lower sperm concentration.[139,140] The causal effects of environmental exposure on male reproductive processes can be demonstrated in animal models. The direct testing of the effects of environmental exposure on male reproductive function in men is not possible. Data derived from epidemiology studies show inconsistent association of exposure to endocrine disruptors with semen quality or reproductive developmental defects in men.[141]

Male Infertility and Testicular Cancer. Testis cancer has been linked to environmental exposure to endocrine disruptors.[71,141] There is an increased incidence of testicular cancer in men presenting with infertility (even in the absence of a history of cryptorchidism).[142] In a case-control study, a prior diagnosis of infertility was associated with an increased risk of testicular cancer (odds ratio [OR] 2.4).[143] In another infertility registry cohort case-control study, men with known male factor infertility had 2.8-fold higher chance of developing a testicular cancer.[144] Testicular cancers are mainly derived from germ cells and occur in young adults. Men with poor semen quality have a much higher risk of testicular cancer (up to 20-fold). Endocrine disruptors with estrogenic or antiandrogenic activity may affect development of both the somatic and germ cells and predispose to infertility and testicular cancer. Cryptorchidism is associated with azoospermia and oligozoospermia and significantly increased the risk of testicular cancer. While no common genetic factors have been identified between impaired sperm production and testis cancer, a recent study based on bioinformatics analyses has suggested the existence of shared genetic factors between oligo-/azoospermia and general cancer predisposition, including testis cancer.[144]

Cigarette Smoking

Data on cigarette smoking and its possible effect on sperm counts are inconsistent. In a meta-analysis of 20 observational studies, men who smoked cigarettes were more likely to have lower sperm counts, motility, and normal morphology.[145] The possibility that *in utero* exposure to smoking may have a detrimental effect on sperm count in adulthood was studied in 1770 young, healthy potential military recruits; the results showed the possibility of a small detrimental effect.[146] In a second related study, there were no significant differences in mean sperm concentrations in men whose mothers smoked or not during pregnancy.[147] Smoking has been shown to change DNA methylation patterns[148] and micro-RNA content in spermatozoa.[149] The significance of this finding, if any, on infertility and progeny is not known.[150] It is advisable that men should stop smoking for fecundity and smoking-related health reasons.[151]

Cell Phone

Because of the rapid increase in cell phone use around the world, studies investigating whether cell phone usage and associated electromagnetic field has a detrimental effect on sperm parameters, are ongoing. This issue is controversial with definitive data not yet available.[152]

Scrotal Hyperthermia

Prolonged high testicular temperature may explain the infertility associated with spinal cord injuries, varicocele, and chronic sauna and Jacuzzi exposure.[153] Studies in men have shown that small increases in testicular temperature accelerate germ cell loss through apoptosis.[154] Similarly, febrile illness, prolonged sitting during work or truck driving, welding, baking, tight-fitting underwear, and laptop use with increased heat to the testes have been proposed to adversely affect male fertility. The data to support these associations are inconsistent and may be a very weak risk factor for infertility.[155]

KEY POINTS

- Though it is debatable whether obese men have higher risk of having abnormal semen analyses and male infertility, for health reasons lifestyle modifications are recommended for infertile couples seeking fertility treatment.
- Environmental exposure to endocrine disruptor *in utero* may result in male reproductive developmental defects such as cryptorchidism, hypospadias, and poor semen quality and testicular cancer. Data are from experimental studies in rodent models and epidemiological association studies in men.
- Men with poor semen quality have higher risk of testis cancer suggesting common factors (environmental and/or genetic) involved in both conditions.
- Cigarette smoking and scrotal hyperthermia should be avoided for men with infertility problems for general health reasons and possible risk for poor semen quality.

EPIGENETICS AND MALE INFERTILITY

With the advent of whole-exome sequencing, many new genetic factors have been identified in the past few years as monogenetic defects causing spermatogenesis dysfunction and male infertility.[156] Much less is known about the contribution of epigenetics to male infertility. Data are sparse and inconsistent, and epigenetic analyses are not used clinically for the clinical diagnosis of male infertility. Nevertheless, epigenetic modifications may alter the expression of genes involved in spermatogenesis theoretically leading to its impairment. Sperm epigenetic modifications such as changes in DNA methylation, histone modification (protamine in sperm), chromatin structure, and noncoding RNA expression may not only affect reproductive function of men but also their progeny.[71,157–159] Modifications of DNA methylation and noncoding RNAs have been implicated in environmental effects on sperm quality (e.g., obesity, smoking)[148,160–162] and in transgenerational effects of pesticides and plasticizers on offspring.[71] Large-scale studies have identified sperm micro-RNAs species and DNA methylation signatures in men with infertility.[163,164,165] Deploying epigenetic biomarkers of male infertility to discover new causes of infertility will require specialized laboratory with technical and bioinformatics capabilities to decipher the epigenetics data and to relate to clinical phenotype and genetics profiling that is not currently used in diagnosis and management of male infertility.[166]

KEY POINTS

- Sperm epigenetics may be associated with male infertility and health of the progeny.
- The importance of epigenetic sperm biomarkers is under investigation but not currently used in clinical practice.

SUMMARY AND FUTURE DIRECTIONS

Male infertility is a common problem that affects 2.5% to 12% of all men globally. Identification of HPT axis abnormalities is important because these conditions may be treatable with medical and surgical approaches. Many testicular causes of infertility do not have specific treatment but recent advances in molecular genetics allow the identification of genes responsible for specific defects of spermatogenesis that may be treatable in the future. The genetics of male infertility are complex but important as they account for about 20% to 30% of the causes of male infertility.[156] The common causes include chromosomal aneuploidy and translocations, Y chromosome microdeletions, monogenetic mutations responsible for quantitative and qualitative spermatogenesis defects, and other causes of endocrine male infertility. Epigenetic modification of gene expression in spermatozoa may provide explanation in some men with idiopathic infertility and may be the conduit for the environmental effects on spermatogenesis.

The challenge for clinicians and investigators in the field of male infertility is the ability to identify the cause of male infertility in each infertile man. Starting with definition of the clinical phenotype, accurate and reproducible sperm quality assessment, hormone measurements, ultrasound imaging, coupled with comprehensive modern genetics, and causative diagnosis are made in about 50% to 60% of infertile men. Coupling the current genetic tools with the impact of epigenetic modifications, proteomics and metabolomics defects may be assessed using bioinformatics toolbox to integrate the information to resolve the etiology of male infertility. However, these assessments at the present required technical expertise concentrated in a few centers that would be restrictive and not available to all patients. Based on each etiology identified, the future is to develop panels of biomarkers that can be used to specifically identify spermatogenesis defects and specific treatment for each infertile man.[167,168] In the meantime, environmental factors such as obesity, cigarette smoking, endocrine disruptors, and others should be eliminated to allow optimization of spermatogenesis and the health of the future progeny.

INTRODUCTION

Infertility, defined as the inability to conceive after 12 months of regular, unprotected intercourse, affects 8 million couples in the United States, of which up to 50% have a male contributory factor.[1,2] Overall, up to 12% of men of reproductive age worldwide suffer from male infertility.[3] Fortunately, a tremendous increase in our understanding of male infertility and our ability to provide novel diagnostic and therapeutic approaches has occurred over the past 50 years. Of note, advanced reproductive technologies such as *in vitro* fertilization (IVF) and intracytoplasmic sperm injection (ICSI) have both enabled men for whom fatherhood could be achieved previously only through donor sperm or adoption to now father biological offspring as well as to provide greater insight into the role of sperm in the outcomes of fertility treatment.

HEALTH CONSIDERATIONS FOR INFERTILE MEN

Progressive accumulation of data has indicated that men who are diagnosed as being infertile or identified as having impaired semen parameters (oligospermia) may be at increased risk of medical conditions later in life, including testicular cancer.[4] For example, men who require treatment with assisted reproduction for male factor infertility are at increased risk of subsequent development of prostate cancer.[5] Men with azoospermia are at increased risk of several different types of cancer later in life, so routine screening or follow-up for cancer should be considered after fertility treatment.[6] Men with infertility are also at increased risk of comedical conditions including obesity, diabetes, and hyperlipidemia, so men may reach medical care because of an infertility diagnosis and evaluation.[7] Obviously, follow-up management of these other comorbidities is needed for long-term health optimization. In addition, a specific diagnosis (e.g., diagnosis of Klinefelter syndrome) may result in certain risks of disease, including extragonadal germ cell tumor, breast cancer, and metabolic syndrome. Conditions associated with infertility such as low testosterone are also associated with other medical conditions, including diabetes, metabolic syndrome, cardiovascular disease, hypertension, all-cause mortality, and Alzheimer's disease.[8]

KEY POINTS

- Infertile men, especially those with azoospermia, are at increased risk of cancer and other medical comorbidities.
- Counseling regarding these risks is indicated after treatment of infertility. Specific risks associated with conditions causing infertility, such as Klinefelter syndrome, are also needed (see Chapter 107).

Recommendations from the American Urological Association and the American Society for Reproductive Medicine advocate that initial evaluation of the infertile couple includes investigation of both partners in parallel.[9] In this chapter, we provide an updated outline of evaluation and treatment algorithms that guide the management of the infertile male.

Evaluation of Male Infertility

When and on Whom to Perform an Evaluation of Male Infertility. An initial screening evaluation on both partners is recommended if a couple has not conceived a pregnancy after 12 months of regular,

BOX 113.1 Significant Medical Conditions That May Present as Male Infertility[84,85]

Adult polycystic kidney
Brain tumors
Cystic fibrosis
Diabetes
Hemochromatosis
Hypopituitarism
Klinefelter syndrome
Multiple sclerosis
Pituitary adenoma
Prostate cancer
Retroperitoneal tumors
Spinal cord tumors
Testis cancer
Thyroid disease
Urinary tract infection

unprotected intercourse. Alternatively, an earlier evaluation is justified if the female partner is older than 35 years old, if either partner has a medical history or physical findings suggestive of decreased reproductive potential, or if either partner is concerned about the male's reproductive potential. Men who do not have a partner but who are concerned about their reproductive potential should also undergo an initial screening evaluation.

The goals of the evaluation of male infertility are to identify and treat correctable causes of male infertility that could then result in natural pregnancy, to guide treatment options in those for whom natural pregnancy is unlikely to occur, and to identify significant medical problems that are associated with infertility (Box 113.1).

Initial Screening Evaluation

KEY POINTS

- Initial screening evaluation for male infertility should involve a reproductive history and at least one semen analysis.
- For men with abnormalities on initial evaluation, a complete history, physical examination, and at least two semen analyses are needed (see Chapter 116).
- While abnormalities on semen analysis are not diagnostic of male infertility, semen analysis is a cornerstone in the evaluation of male infertility.
- Abnormalities on semen analysis are more predictive of infertility if there are multiple abnormal semen parameters.

History and Physical Examination

A thorough reproductive history (Table 113.1) is a critical component of the initial screening evaluation of the infertile male and should cover coital frequency and timing, duration of infertility, prior fertility, developmental history and childhood illnesses (including hypospadias, congenital anomalies, and onset of puberty), current systemic illnesses (especially diabetes mellitus, cystic fibrosis, cancer, and infections), surgical history (with a focus on scrotal, pelvic, retroperitoneal, and inguinal surgeries), sexual history (with a history of sexually transmitted diseases), medications and allergies, and exposure to gonadotoxins (both chemical and environmental toxins such as heat; see Table 113.2). Additionally, a family history of cryptorchidism, infertility, disordered sexual differentiation, or hypogonadism and/or a social history with frequent alcohol, tobacco, or recreational drug use may suggest potential etiologies for male infertility and lead to further evaluation.

A general physical examination with an emphasis on the genitalia can provide additional important information on conditions that can affect male fertility. Upon initial inspection,

note should be taken of obesity, secondary sex characteristics, hair distribution, and gynecomastia. Specific examination of the genitalia should include the phallus, which should be examined for hypospadias, penile curvature, and plaques that may interfere with proper semen deposition within the vagina. Both testes should be examined for size, consistency, and the presence of masses. Over 70% of human testicular volume is made up of seminiferous tubules in which spermatogenesis occurs and testicles smaller than the normal adult size of 20 mL (or 4.5 cm × 3 cm) may be associated with impaired spermatogenesis.[10]

Careful attention should be paid to the presence, consistency, and nodularity of the epididymides that may help to identify obstruction and/or infection while palpation of both vasa deferens can diagnose vasal agenesis, atresia, or injury. Congenital bilateral absence of the vas deferens (CBAVD) is a clinical diagnosis that should be made on physical examination. Palpation of both spermatic cords in the supine and standing positions with and without Valsalva enables the diagnosis of varicocele, which is also a clinical diagnosis. Scrotal ultrasound may be used to confirm diagnosis of varicocele, but those subclinical varicoceles found only on ultrasound (and not on physical examination)

TABLE 113.1 Important Parts of the Male Infertility History

Infertility History
- Duration
- Prior pregnancies
    - Current vs previous partner
    - Outcome
- Prior fertility evaluation

Sexual History
- Coital frequency and timing
- Erectile function
- Use of lubricants

Past Medical History
Developmental History
- Cryptorchidism
- Puberty
- Testicular pathology (e.g., trauma or torsion)
- Hypospadias

Medical History
- Diabetes mellitus
- Neurologic disease (spinal cord injury, multiple sclerosis)
- Fevers or infections (urinary, sexually transmitted, tuberculosis, prostatitis)
- Cancer and treatment (chemotherapy or radiation)
- Genetic disease (Klinefelter, cystic fibrosis)

Surgical History
- Genital (orchidopexy, testicular trauma, vasectomy)
- Pelvic (herniorrhaphy, prostatic, bladder neck)
- Abdominal/retroperitoneal

Family History
- Infertility
- Cryptorchidism
- Disorders of sexual differentiation
- Midline defects
- Cystic fibrosis

Medications
Social History
- Recreational drugs (smoking, alcohol, marijuana, cocaine)
- Environmental/occupational exposure (pesticides, radiation, heavy metals, heat)

TABLE 113.2 List of Agents and Factors With Potential Adverse Impact on Male Fertility

Medications

- Gonadotoxic agents
  - Antibiotics
  - Nitrofurantoin
  - Erythromycin
  - Tetracycline
  - Gentamycin
  - Sulfasalazine
  - Chemotherapeutic agents
  - Alkylating agents (cyclophosphamide, ifosfamide)
  - Cisplatin
  - Actinomycin D
  - Marijuana
  - Alcohol
- Androgen production inhibitors
  - Spironolactone
  - Ketoconazole
  - Cimetidine
  - Flutamide
  - 5α-reductase inhibitors
- Ejaculatory dysfunction
  - Alpha-blockers
  - Lithium
  - Antipsychotics
  - Tricyclic antidepressants
  - Valproic acid
  - Phenytoin
  - SSRIs
- Asymptomatic sperm DNA damage
  - SSRIs
- Hypothalamus–pituitary–gonadal axis inhibitors
  - Testosterone
  - Anabolic steroids
  - Monoamine oxidase inhibitors
  - Phenothiazines
  - DES
  - Digoxin
  - Alcohol
  - Opioids
- Sperm toxic agents
  - Nicotine
  - Calcium channel blockers
  - Sulfasalazine

Environmental

- Heavy metals (lead)
- Pesticides (dibromochloropropane)
- Heat
- Bisphenol A
- Organic solvents
- Ionizing radiation

DES, Diethylstilbestrol; *SSRI,* selective serotonin reuptake inhibitor.

are unlikely to be clinically relevant.[9] Finally, digital rectal examination may help identify dilated seminal vesicles, ejaculatory duct cysts, or utricular cysts that may contribute to obstructive etiologies of male infertility, such examination is most relevant for men with abnormal semen volume.

TABLE 113.3 WHO (5th Edition) Reference Values for Semen Analysis[29]

Semen Analysis Parameter	Reference Value
Ejaculate volume	1.5 mL
Sperm concentration	15 million sperm/mL
Sperm count	39 million sperm/ejaculate
Total motility	40%
Total progressive motility	32%
Sperm morphology	4% normal (strict criteria)
Sperm viability	58%
Sperm agglutination	Absent
White blood cells	<1 million leukocytes/mL

Semen Analysis

Along with a thorough history and physical examination, semen analysis has long been the pillar upon which male infertility is evaluated and managed. While an abnormal semen analysis (with the exception of azoospermia) cannot delineate between fertile and sterile, abnormal semen quality is associated with decreased chances of natural conception.[11]

To account for the large degree of biological variability between semen samples, at least two semen analyses should be performed. Because environmental exposures can change over time and spermatogenesis takes more than 2 months, repeat semen samples after a month or more may be needed to validate abnormal semen parameters. Patients should be given specific instructions regarding the need for 2 to 5 days of abstinence prior to undergoing semen analysis with the two semen analyses.[14] Although the standard abstinence period is important for comparison of samples to "normal" standards, it is possible that men with low sperm production, such as those with severe oligospermia, may actually have better semen parameters with very short abstinence, even abstinence of a few hours. Indeed, men with severe oligospermia or cryptospermia may benefit from providing multiple semen specimens within hours, especially for assisted reproductive treatments such as IVF/ICSI.

A semen sample can be collected either by masturbation into a specimen cup or by intercourse with the use of a special semen collection condom that does not contain any spermatotoxic agents. In particular, lubricants should be avoided. If a specimen cannot be produced at the laboratory for analysis, it should be kept at room or body temperature during transport and delivered to the laboratory for analysis, preferably within 1 hour. Further delays can affect semen and sperm parameters such as sperm motility, which may decrease dramatically after 2 hours.

Parameters examined in routine semen analysis can be broken up into macroscopic and microscopic parameters. Key macroscopic parameters include semen volume, viscosity, color, pH, and coagulation/liquefaction, while key microscopic parameters include sperm count/concentration, sperm motility, and sperm morphology. After analyzing the semen analyses of 1859 new fathers from eight countries across three continents, the World Health Organization (WHO) established the normal reference ranges for most of the key parameters of semen analysis (Table 113.3).[15] To establish the reference ranges, the WHO applied a one-sided lower reference limit of the 5th percentile to the semen parameters of the 1859 new fathers. While this methodology provides lower thresholds for semen parameters in fertile men, it fails to answer the more relevant clinical question of which specific semen parameters and cutoffs are able to delineate between male fertility and subfertility. Efforts to identify specific semen parameters that can distinguish between male fertility and subfertility have instead found that while semen parameters are associated with fecundity, neither sperm concentration, morphology, nor motility could be considered diagnostic of infertility either alone or in combination.[13,16] Rather than a direct diagnostic test of male infertility, the semen analysis should instead be considered an important contributor to the overall picture of male fertility. The presence of multiple semen parameter abnormalities, especially low sperm concentration, motility, and morphology, may have the greatest effects on fertility potential.

Further Investigations and Complete Evaluation

KEY POINTS

- Further investigations of male infertility are directed by the initial evaluation. Critical abnormal semen parameters may include detection of low semen volume, oligoasthenoteratospermia, or azoospermia.
- Endocrine evaluation of male infertility should include, at a minimum, serum testosterone and follicle-stimulating hormone (FSH). Low serum testosterone should be further evaluated with LH determination; men with abnormal libido or hypogonadotropic hypogonadism should be considered for testing with serum prolactin evaluation.

Men with an unremarkable reproductive history and normal semen analysis(es) are highly unlikely to harbor male infertility and a greater focus on potential female factors should be undertaken. However, if any abnormalities are detected on the initial screening evaluation of male infertility, further investigation, as discussed previously, is indicated.

Endocrine Evaluation

While a specific endocrine cause of impaired sperm production is identified in only 2% to 5% of men with male factor infertility, endocrine evaluation is indicated for men with abnormal semen analyses (especially in those with sperm concentrations <10 million/mL), abnormal sexual function, or other findings suggestive of endocrinopathy.[9,17] At minimum, an endocrine evaluation for male infertility should include serum FSH and morning testosterone levels. A low serum testosterone level (<300 ng/dL) should prompt the testing of a second morning serum testosterone level alongside serum luteinizing hormone (LH) and prolactin levels.[18] The importance of obtaining a second morning serum testosterone level should not be understated as gonadotropins and testosterone are typically released in a pulsatile manner and testosterone levels commonly demonstrate a physiologic variation over the course of the day with the highest levels in the early morning. The characteristic hormone profiles for various etiologies of male infertility are described in Table 113.4. In particular, while normal FSH levels (≤7.6 IU/L) do not guarantee normal spermatogenesis, elevated FSH levels often indicate an abnormality with spermatogenesis.[18]

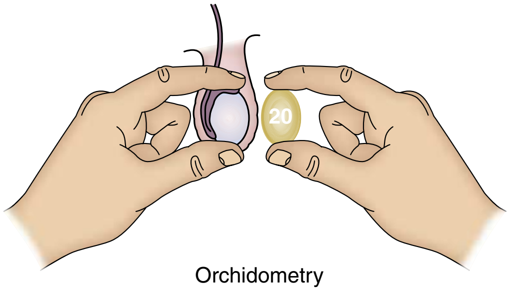
Low Semen Volume

KEY POINTS

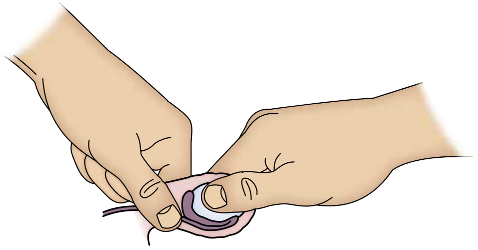
- Low semen volume may be attributable to ejaculatory dysfunction, hypogonadism, ejaculatory duct obstruction, or CBAVD, as well as incomplete semen collection.
- An endocrine evaluation, postejaculatory urinalysis, and transrectal ultrasound can help identify the cause of low semen volume.

TABLE 113.4 Characteristic Hormone Profiles for Various Etiologies of Male Infertility

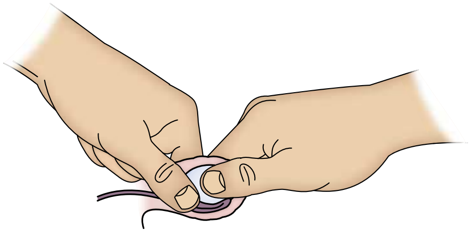
Condition	Testosterone	FSH	LH	Prolactin
Normal	Normal	Normal	Normal	Normal
Primary Testicular Failure				
• Hypospermatogenesis	Normal/low	High	High/normal	Normal
• Maturation arrest	Normal	Normal	Normal	Normal
• Sertoli cell only	Low	Very high	High	Normal
Hypogonadotropic hypogonadism	Low	Low	Low	Normal
Hyperprolactinemia	Low	Normal/low	Low	High
Klinefelter syndrome	Low	Very high	High	Normal



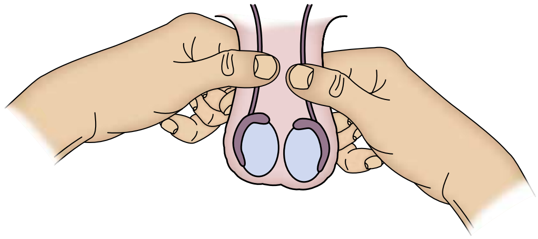
Orchidometry



Palpatation of testis



Palpatation of epididymis



Checking for varicocele

Figure 113.1 Clinical Examination of the Scrotum.

Postejaculatory Urinalysis

The presence of low semen volume (<1.0 mL) should prompt a systematic algorithm to delineate the cause (Fig. 113.1). Potential etiologies for low semen volume include incomplete semen specimen collection, CBAVD, hypogonadism, ejaculatory dysfunction, and ejaculatory duct obstruction. In men with normal serum testosterone levels and palpable vasa deferens, a postejaculatory urinalysis should be performed to rule out retrograde ejaculation. The presence of more sperm than in the urine specimen pellet postejaculation is suggestive of retrograde ejaculation.[15]

Transrectal Ultrasound

Transrectal ultrasound (TRUS) has limited indications for the evaluation of male infertility. Only in the case of significantly low semen volume (<1.0 mL) that is not explained by vasal agenesis, low serum testosterone, retrograde ejaculation, or incomplete collection, should TRUS be considered. The absence of seminal fructose or a seminal pH <7 may also suggest the absence/atrophy of the seminal vesicles or ejaculatory duct obstruction. The diagnostic tool of choice for ejaculatory duct obstruction is TRUS. The presence of midline cysts, dilated seminal vesicles (anterior-posterior diameter >1.5 cm), or dilated ejaculatory ducts (>2.3 mm) on TRUS is suggestive, but not diagnostic, of complete or partial ejaculatory duct obstruction.[16,17] If dilated seminal vesicles are seen on TRUS, TRUS-guided seminal vesicle aspiration may be performed to confirm the diagnosis (with simultaneous cryopreservation of any sperm found).[18] Patients with unilateral absence of the vas deferens and low volume azoospermia may have a variant of CBAVD and should undergo genetic screening for cystic fibrosis (CFTR) before TRUS. Forty percent of men with CBAVD and a negative CFTR screen will demonstrate renal anomalies and should be additionally screened with abdominal ultrasound. On the other hand, those with CBAVD and a positive CFTR screen are at lower risk of renal.[19,20] Men with detectable CFTR mutations should undergo thorough genetic counseling, and their female partner must be tested for genetic abnormalities prior to any fertility treatment, as recommended by the American College of Obstetricians and Gynecologists (ACOG) guidelines for preconceptual counseling.

Oligospermia/Asthenospermia/Teratospermia

KEY POINTS

- Oligoasthenoteratospermia may be caused by varicocele, genetic abnormalities, immunologic infertility, or gonadotoxic exposures.
- Genetic testing with karyotype and Y-microdeletion testing is indicated in men with severe oligospermia (<1 million sperm/mL) or nonobstructive azoospermia (see Chapter 112).
- Genetic testing with CFTR gene mutation analysis is indicated for men with Wolffian abnormalities, including CBAVD.

Infertile men may demonstrate abnormalities in sperm concentration (oligospermia), motility (asthenospermia), and/or morphology (teratospermia), which are often seen together. Potential causes for these abnormal semen parameters include endocrinopathies, genital tract infections, immunologic antisperm antibodies (ASA), varicoceles, and genetic abnormalities (Fig. 113.2).

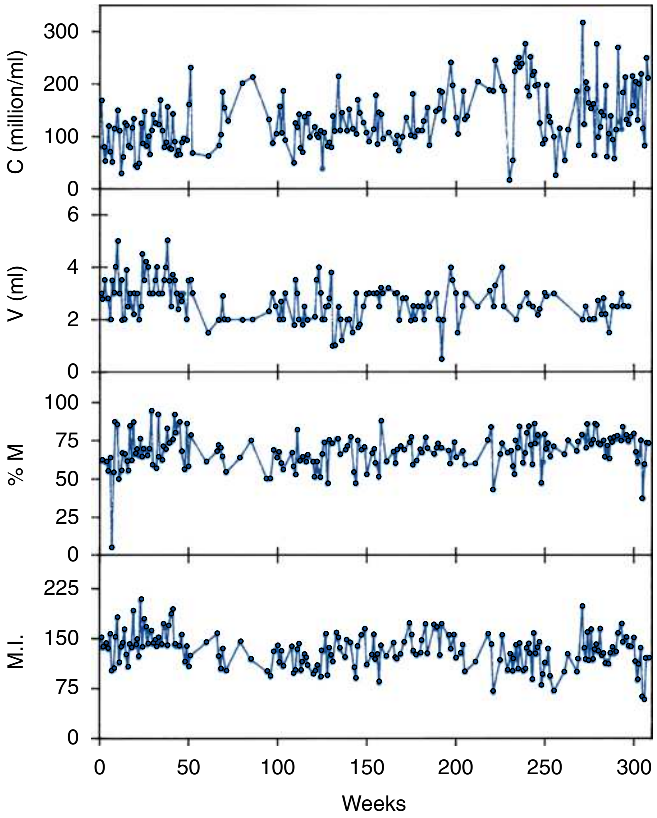


Figure 113.2 Variability of Semen Analysis Results in a Fertile Sperm Donor. C, Sperm concentration; M, total motility; M.I., motility index—product of grade and percentage of sperm with progressive motility graded 0 to 3; V, semen volume. (Data from Mallidis C, Howard EJ, Baker HW: Variation of semen quality in normal men, Int J Androl 14:99–107, 1991. Used by permission, Blackwell Scientific Publications.)

KEY POINTS

- Antisperm antibody testing and routine semen cultures are not indicated for the initial evaluation of male infertility.

Semen Leukocytes and Screening for Genital Infection

Routine semen cultures do not have value in the evaluation of male infertility. However, genital tract infection or inflammation may result in the presence of leukocytes in the semen that can negatively affect sperm motility and function via the overproduction of reactive oxygen species as well as direct effects on spermatozoa. Because both leukocytes and immature germ cells appear as “round cells” on microscopy, differentiating between the two types of cells can be tricky but can be accomplished using cytologic staining or immunohistochemistry.[21] Those with pyospermia (>1 million leukocytes/mL) should be evaluated further to rule out or treat genital tract infection or inflammation. Because 83% of semen cultures in asymptomatic infertile men with pyospermia are positive with multiple organisms, the evaluation may include an examination of expressed prostatic secretion for leukocytes as well as a urethral culture (or urine ligase chain reaction [LCR] test) for Chlamydia and Mycoplasma.[22]

Antisperm Antibodies (ASA)

Patients with isolated asthenospermia or sperm agglutination may be bound by ASA, which is a rare cause of male infertility that can form following a breach of the blood–testis barrier after vasectomy, trauma, torsion, biopsy, or testicular cancer. Routine testing for ASA is not indicated in the evaluation of male infertility as the condition is rare, and the presence of ASA may not affect management of infertility. ASA can be a diagnostic test for obstruction in azoospermic men. Approximately 50% to 80% of men with obstructive azoospermia (OA) have ASA detectable in serum. ASA can be found in the serum or seminal plasma via indirect antibody agglutination assays or directly bound to the sperm via a direct immunobead test. ASA are considered significant if over 50% of sperm are bound by ASA.[23] Because the presence of ASA correlates with spermatogenesis, the detection of serum ASA may also be clinically useful in differentiating azoospermic men with obstructive etiologies versus those with nonobstructive etiologies without the need for a diagnostic testicular biopsy.[24] Azoospermic men with positive ASA are more likely to have an obstructive etiology, with the presence of ASA having an 85% specificity for obstruction.[25]

Genetic Testing (see Chapter 112)

Genetic abnormalities can cause problems with sperm production or transport and men with severe oligospermia (sperm concentration <1 million/mL) or non-OA (NOA) should be worked up for genetic abnormalities (Table 113.5).[4] In addition to the previously discussed CFTR mutations, karyotypic chromosomal abnormalities and Y-microdeletions are of concern. In total, genetic abnormalities are estimated to account for 15% to 30% of male infertility, though the overwhelming majority of these abnormalities have yet to be discovered or understood.[26]

Chromosomal abnormalities are more common in infertile men, with the prevalence of chromosomal abnormalities inversely proportional to sperm count. Ten to fifteen percent of azoospermic men harbor chromosomal abnormalities compared with 5% of men with severe oligospermia and <1% of men with normal sperm concentrations.[27,28] The most common chromosomal abnormality in infertile men is 47,XXY (Klinefelter syndrome), though inversions and balanced translocations are also more prevalent in infertile men when compared with fertile men.[28]

Deletions of clinically relevant sections from the azoospermia factor regions (AZF) on the long arm of the Y chromosome (Yq11) are found in up to 17% of men with non-OA or severe oligospermia.[25] These Y-microdeletions can be categorized by their specific locations, which are prognostic of their ultimate impact on spermatogenesis and infertility. Men with deletions in the AZFa or AZFb regions are azoospermic with a near 0% chance for successful sperm retrieval.[30] In contrast, men with deletions in the AZFc region may have severe oligospermia while 65% to 75% of those with azoospermia produce sufficient sperm for testicular sperm extraction and use in ICSI.[30]

KEY POINTS

- Sperm DNA fragmentation is not required in the initial evaluation of male infertility.
- Couples with recurrent miscarriage or failed IVF may benefit from sperm DNA fragmentation testing, as it could identify the cause of their infertility problem.

Sperm DNA Fragmentation

The standard semen analysis has a limited ability to predict male fertility, except in azoospermia or specific, uniform abnormalities

TABLE 113.5 **Common and Known Genetic Abnormalities in Male Infertility[86–88] (see Chapter112)**

Genetic Abnormality	Phenotype	Frequency
Chromosomal Abnormality		
• Klinefelter syndrome (47,XXY)	• NOA, sperm retrieval rate up to 65% at micro-TESE • Hypogonadism	1:500 of newborn males
• 47,XYY	• Often phenotypically normal with variable sperm counts (normozoospermia to azoospermia)	1:1000 of newborn males
• 46,XX male	• Azoospermia with Sertoli–cell-only testicular histopathology	1:20,000 of newborn males
• Chromosomal translocations/ inversions	• Autosomal inversions can result in phenotypically normal males, but with oligospermia or azoospermia • Robertsonian translocations can cause recurrent miscarriage and/or offspring with genetic abnormality	1:600 to 1:1000 of newborn males
YCMD		10% to 15% of men with severe oligospermia or NOA
AZFa	• Azoospermia and Sertoli–cell-only pattern on testicular histopathology • Sperm retrieval rate 0% with micro-TESE	2% to 5% of YCMD
AZFb	• Azoospermia and uniform maturation arrest pattern on testicular histopathology • Sperm retrieval rate 0% with micro-TESE	13% to 16% of YCMD
AZFc	• Severe oligospermia to azoospermia • Sperm retrieval rate of up to 70% with micro-TESE	60% to 75% of YCMD
Combination deletions	• Azoospermia with very poor sperm retrieval prognosis if AZFa or AZFb regions involved	10% to 14% of YCMD
Single Gene Mutations		
• CFTR gene mutations	• OA due to congenital bilateral absence of vas deferens • Clinical cystic fibrosis may also have chronic pulmonary obstruction/infection and pancreatic insufficiency	1:25 carriers, 1:2500 of live births
• Kallman syndrome (KAL1, FGFR1, and others)	• Hypogonadotropic hypogonadism • Range of testicular histopathology with the recovery of spermatogenesis following hormonal treatment	1:30,000 of live births
• AR gene mutations	• Varies depending on the severity of AR deficiency • Female phenotype and Sertoli–cell-only in AR-negative or low AR patients • Male phenotype with infertility for AR-positive patients • Intact spermatogenesis for abnormal AR patients	1:60,000 of live births
• INSL3-LGR8	• Cryptorchidism	4% to 5% of newborn males

AR, Androgen receptor; *NOA,* nonobstructive azoospermia; *OA,* obstructive azoospermia; *TESE,* testicular sperm extraction; *YCMD,* Y-chromosome microdeletions.

such as globozoospermia. Efforts to identify sperm characteristics that may provide unique insights into the functional contributions of male gametes led to the application of sperm DNA fragmentation testing. Sperm DNA damage is rarely seen in fertile males but can be found in 8% of infertile men with normal semen analyses and 17% of infertile men with abnormal semen analyses.[31] Causes of sperm DNA damage may include intrinsic causes such as abnormalities in DNA compaction and protamine deficiency or extrinsic causes such as heat, gonadotoxins, varicocele, smoking, and radiation. Clinical observations have elucidated that sperm DNA damage occurs during sperm transport after sperm have left the testis. These observations include the increased sperm DNA damage in men with defects in sperm transport, including men with ejaculatory dysfunction associated with spinal cord injury or other abnormalities, increased sperm DNA damage after ineffective microsurgical reconstruction of the male reproductive tract, and for men who have received selective serotonin reuptake inhibitors (SSRIs). Several assays have been used to measure sperm DNA fragmentation, including direct assays like Comet gel electrophoresis and terminal deoxynucleotidyl transferase–mediated deoxyuridine triphosphate-nick end labeling (TUNEL) and indirect assays such as sperm chromatin structure assay (SCSA) and sperm chromatin dispersion (SCD). Although studies on male contributions to fertility are subject to substantial heterogeneity and bias because of the confounding effects of important female factors, existing evidence supports a substantial role for sperm DNA fragmentation in predicting IVF and ICSI outcomes, with elevated sperm DNA fragmentation associated with decreased assisted reproductive technique (ART) success rates for clinical pregnancy. Even more dramatic are the effects of abnormal sperm DNA fragmentation of miscarriage rates. Adverse effects of sperm DNA fragmentation are detectable for both IVF and ICSI.[32–34]

Other Genetic Anomalies

While thousands of genes have been implicated in affecting spermatogenesis, our understanding of their causative roles in male infertility is still in nascent stages.[35] However, advances in genetic evaluations including next-generation whole-exome or whole-genome sequencing, single nucleotide polymorphism (SNP) arrays, and array comparative genomic hybridization analysis improve our understanding of specific gene defects on male infertility by enabling the study of multiple genes in parallel. For example, investigation of asthenozoospermic men with primary ciliary dyskinesia has enabled the identification of new genetic abnormalities that impair the axoneme's structure and function (DNAI1, DNAI2, DNAAF1/LRRC50, DNAAF2/Ktu, LRRC6, ZMYND10, CCDC40).[36]

Other genes known to cause male infertility include the X-linked KAL1 and the autosomal FGFR1, which both result in idiopathic hypogonadotropic hypogonadism (HH), or Kallman syndrome when also associated with anosmia.[37] Genes causing teratozoospermia include Aurora kinase c, which has been found to cause macrozoospermia particularly in North African men, and SPATA16, PICK1, and DPY19L2, which have been shown to cause globoozospermia.[38,39]

In addition to the aforementioned single gene mutations, promising work is occurring in the field of epigenetics or the regulation of gene expression without modification of the gene sequence. Investigation of various epigenetic processes such as DNA methylation, post-translational histone modification, chromatin remodeling, and micro-RNAs may help unlock the etiology behind many cases of male infertility currently classified as idiopathic and identify new diagnostic and therapeutic strategies for the management of male infertility.

Azoospermia

KEY POINTS

- A critical distinction to make in the evaluation of azoospermia is obstructive versus nonobstructive azoospermia.
- The cause of azoospermia directs genetic evaluation and the prognosis for sperm retrieval and successful fertility treatment.

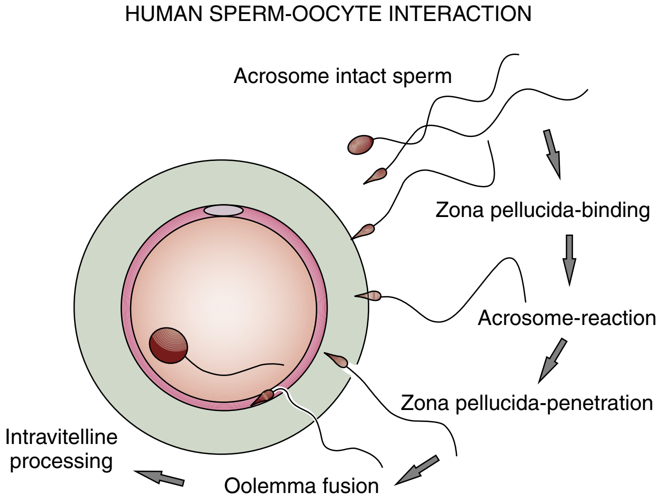
A complete lack of sperm in the ejaculate can be caused by either obstructive etiologies (i.e., ductal obstruction) or nonobstructive etiologies (i.e., testicular failure), which represents the critical distinction to make in the evaluation of men with azoospermia. Using many of the investigations outlined in Fig. 113.3 provides the information necessary to make the diagnosis that will drive the ultimate management of the azoospermic male. In rare equivocal cases where a testicular biopsy is needed to differentiate obstructive from non-OA, it should be performed in the operating room with the surgeon ready to proceed immediately either to reconstruction of the male reproductive tract or to sperm retrieval.

MANAGEMENT OF MALE INFERTILITY

Lifestyle Modifications

KEY POINTS

- Men should discontinue their use of anabolic steroids or exogenous testosterone.
- Potentially effective lifestyle modifications for male infertility include counseling on coital practices, avoidance of spermatotoxic lubricants, smoking cessation, obesity reduction, and decreased exposure to wet heat.
- Evidence to support other lifestyle interventions is very limited, so effective counseling on other lifestyle changes cannot be directed by current data.



HUMAN SPERM-OOCYTE INTERACTION
Acrosome intact sperm
Zona pellucida-binding
Acrosome-reaction
Zona pellucida-penetration
Intravitelline processing
Oolemma fusion

Figure 113.3 Stages of Human Fertilization. Spermatozoa swim through the surrounding medium and cumulus mass *(not shown)* and bind to the surface of the zona pellucida. The acrosome reaction is stimulated by zona proteins, and the acrosome-reacted sperm penetrates the zona, enters the perivitelline space, and binds to the oolemma via the equatorial segment. Oocyte processes surround the sperm head, and it enters the ooplasm and decondenses. Infertility could result from defects in any of these processes. For example, abnormal sperm, particularly with defective head morphology, bind poorly to the zona.

Counseling on coital practices, including the appropriate frequency and timing of intercourse and the avoidance of potentially spermatotoxic lubricants, may be an important and productive intervention for many patients. If required, rather than using many of the commercially available lubricants, Pre-Seed, canola oil, and raw egg white appear to be sperm-friendly coital lubricants.[40,41]

Men using anabolic steroids or exogenous testosterone should be informed of the deleterious impact these medications have on spermatogenesis via inhibition of the pituitary-gonadal hormone axis and counseled to discontinue their use. Similar warnings should be given to men using other medications or recreational drugs known to hinder spermatogenesis (Table 113.2). Smoking, which is linked with decreased semen quality that results in decreased fecundity and lower success rates even with assisted reproduction, should be strongly discouraged.[42–44] Since obesity is associated with decreased semen parameters, weight loss should be encouraged.[45–47] Increased physical activity, which has been shown to improve semen parameters, but not necessarily clinical pregnancy or live birth rates following infertility treatment, should be encouraged.[48]

Routine exposure to wet heat via saunas, hot tubs, or hot baths should be discouraged as it can increase intratesticular temperature and transiently hinder spermatogenesis and sperm quality.[49,50] While an excellent form of aerobic exercise, bicycling, may negatively affect semen parameters due to the increased scrotal temperature associated with scrotal compression against the saddle.[51] Men who biked more than 1.5 hours/week had 34% lower sperm concentrations than those who did not bike.[48] Of note, given that the spermatogenic cycle is typically 60 to 76 days long, recovery from a spermatogenic insult may take up to 3 months to resolve.[52]

Hormone Optimization

KEY POINTS

- Men with low serum testosterone should be treated with medications that will not inhibit the hypothalamic–pituitary–gonadal axis such as selective estrogen receptor modulators or gonadotropins.
- Men with excess estrogen levels may benefit from treatment with aromatase inhibitors .

Treatment of diagnosed hormonal abnormalities to optimize sperm production should occur before more invasive strategies are undertaken. Treatable endocrinopathies include hyperprolactinemia, hypothyroidism, and congenital adrenal hyperplasia. Men with low serum testosterone (<300 ng/mL) should be managed with agents that will increase serum testosterone without suppressing the hypothalamic–pituitary–gonadal axis such as a selective estrogen receptor modulator (SERM) or human chorionic gonadotropin (hCG). A recent meta-analysis reviewing the use of SERM (clomiphene or tamoxifen) in infertile men with oligo and/or asthenoteratozoospermia showed an association between SERM use and increased pregnancy rates (odds ratio [OR] 2.42, $P = 0.0004$) with no significant differences in complication rates between the treated and control groups.[58] Men with HH may benefit from treatment with both hCG to induce intratesticular testosterone production and FSH to stimulate spermatogenesis.[59–62] Another treatment option for men with HH and a functioning pituitary gland is with pulsatile gonadotropin-releasing hormone (GnRH). Patients with excess estrogen levels manifested by low serum testosterone (<300 ng/mL) and decreased testosterone/estradiol ratios (<10) should be treated with an aromatase inhibitor (such as anastrozole, 1 mg P.O. daily), which increases circulating testosterone and decreases estradiol to enhance intratesticular testosterone levels and improve spermatogenesis.[62–64]

Ejaculatory Dysfunction

KEY POINTS

- Retrograde ejaculation may be treated with sympathomimetic medications or with bladder harvest of sperm for use in ART.
- Men with anejaculation may be treated with penile vibratory stimulation or rectal probe electroejaculation.

Retrograde ejaculation diagnosed on postejaculatory urinalysis can be treated with sympathomimetic medications to promote closure of the bladder neck at ejaculation or with bladder harvest of sperm for use in ART. Anejaculation, or lack of ejaculation, can occur in men with pelvic nerve damage from diabetes mellitus, retroperitoneal surgery, multiple sclerosis, spinal cord injury, or psychosocial causes. The use of penile vibratory stimulation (PVS) or rectal probe electroejaculation (EEJ) can help to procure a semen sample containing sperm for use with ART. In particular, PVS, which often does not require general anesthesia, works best in men with complete spinal cord injuries above T10, with up to 86% of patients able to achieve ejaculation with PVS.[65,68] On the other hand, only 0% to 15% of men with spinal cord injuries below T10 were able to achieve ejaculation with PVS.[60,62] In men with anejaculation from other etiologies or after failure with PVS, EEJ is preferred and can produce ejaculation in 92% of men with anejaculation from spinal cord injury.[60] Of note, because both PVS and EEJ can cause autonomic dysreflexia in men with spinal cord injuries at or above T6, blood pressure monitoring and premedication with nifedipine should be considered.[63] If these techniques fail, then surgical sperm retrieval with ART can be employed to circumvent the inability to ejaculate.

Ejaculatory Duct Obstruction

KEY POINTS

- Azoospermic men with ejaculatory duct obstruction may be effectively managed with transurethral resection of the ejaculatory ducts or transurethral ejaculatory duct dilation.
- Another treatment for this condition is sperm retrieval and ART.

Ejaculatory duct obstruction is suspected in men with azoospermia, severe oligospermia, and/or asthenospermia with low semen volume, at least one palpable vas deferens, low semen pH, and negative semen fructose. Once confirmed, ejaculatory duct obstruction can be managed via transurethral resection of the ejaculatory ducts (TURED) or transurethral dilation of the ejaculatory ducts, with 65% of men having significant and durable improvements in semen quality (Fig. 113.4).[64] Potential complications of transurethral management of ejaculatory duct obstruction can occur in 20% to 26% of patients and may include epididymitis, urine reflux into the excurrent ducts, and retrograde ejaculation.[64,65] Given the high complication rates associated with TURED for the management of ejaculatory duct obstruction, it should be reserved for patients who are counseled of its risks and who are unwilling to undergo IVF.

Pyospermia

KEY POINTS

- Increased round cells on semen analysis should be evaluated further to determine whether germ cells or white blood cells (pyospermia) are present in semen.
- Pyospermia should be treated with antibiotic therapy only after culture confirmation of bacterial infection.

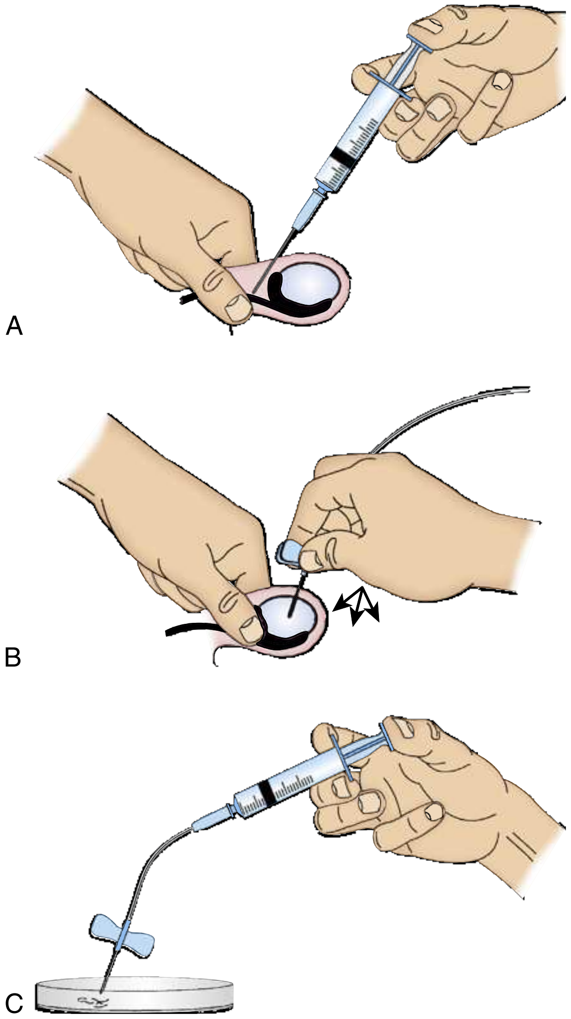


Figure 113.4 Fine-Needle Tissue Aspiration Biopsy of the Testis. A, Local anesthetic is injected around the vas to block testicular sensation. B, A 21-gauge butterfly needle is inserted into the testis. An assistant applies suction to the needle tubing via a syringe, and the operator makes thrusting movements of the needle into the substance of the testis. The appearance of some tissue fluid in the tubing (1 to 2 mm) usually indicates that adequate tissue has entered the needle. While maintaining the suction, the needle is removed carefully, and any seminiferous tubules protruding from the needle are grasped with fine forceps to avoid their falling back into the puncture hole. C, Seminiferous tubule sections sucked into the needle are expelled into culture medium. Portions can be sent for histology or used for extraction of sperm for intracytoplasmic sperm injection (ICSI) by stripping the seminiferous tissue out of the connective tissue membrane of the seminiferous tubule.

Pyospermia associated with a bacteriological infection should be managed with an appropriate course of culture-specific antibiotics. However, without concrete evidence of bacteriological infection, the management of pyospermia is controversial, though a limited course of a broad-spectrum antibiotic such as doxycycline or trimethoprim-sulfamethoxazole along with frequent ejaculation has been shown to decrease semen leukocyte concentration.[66,67]

Immunological Infertility

KEY POINTS

- The effects of antisperm antibodies are effectively managed using ICSI, but evidence suggests that they can also be managed with long-term steroid therapy.

Because the presence of ASA is often associated with obstruction of the genital tract, any lesions should be sought out and corrected. In men with persistent ASA, the management focuses on two broad strategies—immunosuppression or ART. Immunosuppression can be achieved using 6 to 9 months of corticosteroid therapy, which results in consistent reductions in antibody titers and in pregnancy rates ranging from 6% to 50%.[68] The potential complications of long-term steroid therapy are severe and must be accounted for prior to initiation of immunosuppression.[69] Semen can also either be processed in the laboratory in an attempt to remove ASA prior to intrauterine insemination (IUI) or injected directly into an oocyte with ICSI. Due to the potentially significant complications of long-term steroid therapy and the advent of ART, only patients with an objection to IVF should be offered steroid therapy.

Varicocele Repair

KEY POINTS

- Couples with varicocele-associated infertility should be offered varicocele repair when the varicocele is palpable; abnormal semen parameters are documented and no female factors or treatable female factors are present.
- There is no benefit to repairing subclinical varicoceles.
- Microsurgical inguinal or subinguinal repair is the technique of choice for varicocele repair.
- Right varicoceles that are longstanding or decompress in the supine position should not be evaluated further with abdominal imaging.

The decision on whether or not to repair clinical varicocele in the subfertile male remains controversial, though growing evidence suggests a beneficial role for varicocele repair in this population.[12] While meta-analyses trying to answer the question of the impact of varicocele repair on male fertility have been fraught with heterogeneity that make it difficult to draw definitive conclusions, a recent Cochrane subgroup metaanalysis that excluded studies of men with normal semen analyses and/or subclinical varicoceles suggests an association between varicocele repair and improved pregnancy rates.[70] In particular, the evidence suggests that 30% to 50% of infertile couples who are candidates for only ART due to low semen quality may improve to the point of being able to downstage the level of ART needed to conceive or to even enable natural conception following varicocele repair.[71] Currently, the American Society for Reproductive Medicine guidelines suggest varicocele repair for two patient populations: adolescents with reduced ipsilateral testicular size and the infertile couple in which the man has a clinical varicocele, an abnormal semen analysis, and a partner with normal or correctable fertility.[72] On the other hand, the question of whether to repair subclinical varicoceles is less controversial, with the evidence suggesting a minimal benefit to the repair of these varicoceles.[73]

There exist many techniques for varicocele repair, including microsurgical subinguinal or inguinal, open subinguinal or inguinal, retroperitoneal, laparoscopic, percutaneous radiographic embolization, and sclerotherapy. While the success rates between the various techniques are similar, there are differences in the rates of complications such as hydrocele and recurrence (Table 113.6). A metaanalysis from

TABLE 113.6 Summary of Varicocele Repair Techniques[89,90]

Technique	Hydrocele Formation (%)	Recurrence Rate (%)
Open retroperitoneal	6.4 to 10	7 to 35
Open conventional inguinal	7.3	0 to 37
Laparoscopic retroperitoneal	0 to 9.4	2.2 to 6.1
Microsurgical inguinal/subinguinal	0.2 to 1.6	0 to 3.0
Radiographic	0	2 to 24

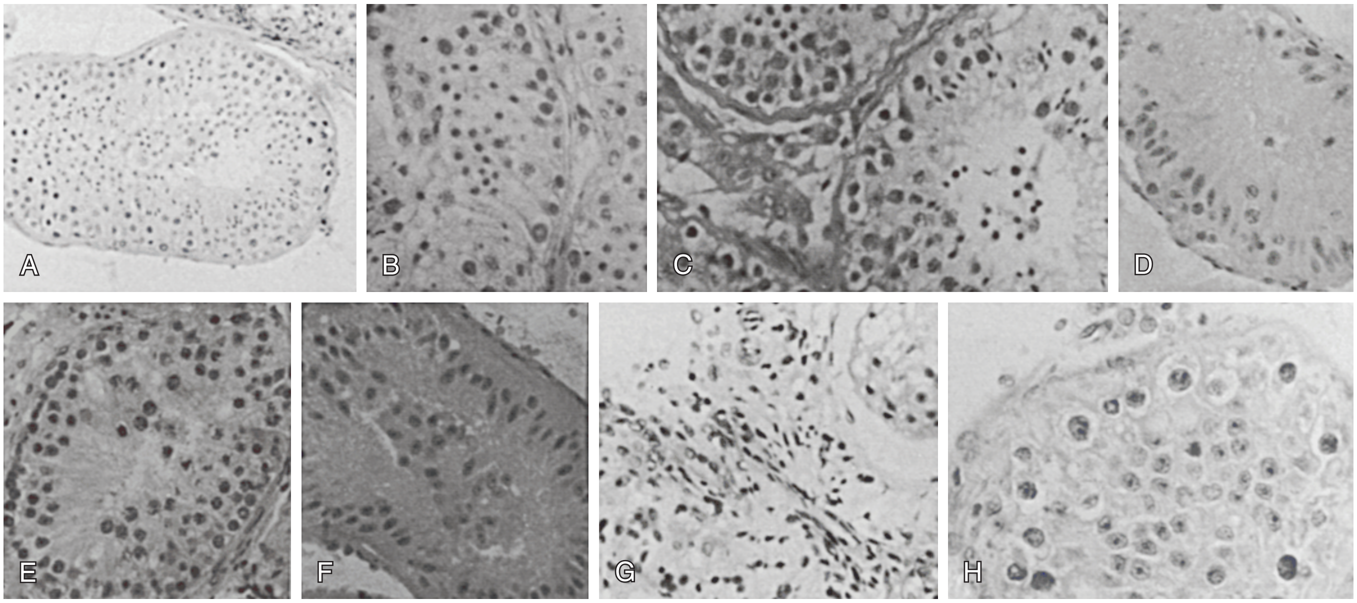

Figure 113.5 Testicular Histology From Fine-Needle Aspiration Samples. **A,** Normal (×200); **B,** mild hypospermatogenesis (×500); **C,** moderate hypospermatogenesis; **D,** severe hypospermatogenesis; **E,** germ cell arrest at the primary spermatocyte stage; **F,** Sertoli-cell–only syndrome; **G,** Leydig-cell tumor in an undescended testis with hyalinized Sertoli-cell–only tubules; H, carcinoma in situ, only transformed spermatogonia and Sertoli cells present.

2009 suggested that microsurgical varicocele repair (Fig. 113.5) was the gold standard for varicocele repair with the lowest rate of both hydrocele (0.4%) and recurrence (1%).[74]

Vasal Reconstruction

KEY POINTS

- Obstructive azoospermia may be treated with vasal reconstruction with either vasovasostomy or vasoepididymostomy as well as sperm retrieval with assisted reproductive technologies.

The most common etiology for OA is vasectomy, though it can also result from iatrogenic injuries (especially after inguinal hernia repair) and idiopathic causes. Of the 7% of American men who report having had a vasectomy, 20% also report a desire for future children.[75]

At the time of vasal reconstruction, if distal and proximal patency is confirmed, then a vasovasostomy is performed, in which the two cut ends of the vas deferens are anastomosed (Fig. 113.6). Seventy to ninety-seven percent of men are likely to have a return of sperm to the ejaculate following vasovasostomy with pregnancy rates ranging from 38% to 93%.[76,77] However, if there is suspicion of secondary epididymal obstruction, then a vasoepididymostomy is performed instead, with the abdominal vas deferens anastomosed to the epididymis (Fig. 113.7). Thirty to ninety percent of men will have a return of sperm to the ejaculate following vasoepididymostomy with subsequent pregnancy rates ranging from 20% to 50%.[78] Due to the delicate nature of both surgeries, almost all vasal reconstructions are performed microsurgically.

Assisted Reproductive Techniques (ART)

KEY POINTS

- ART are effective treatments in the management of the infertile male that should be applied when no specific treatments to correct the male factor are available.
- Different types of ART are recommended for men with differing severities of infertility: IUI for those with moderate infertility, IVF for severe infertility, and ICSI for extreme infertility.
- Sperm can be retrieved from men with non–obstructive azoospermia using microdissection testicular sperm extraction.

For men in whom the aforementioned lifestyle, medical, and surgical strategies fail, ART is the final step. ART can be subdivided into IUI, IVF, and ICSI. From the male perspective, the decision between which ART strategy to use depends primarily on the level of impairment as defined by the number of sperm that can be retrieved (Fig. 113.8). Men with total motile sperm concentrations above 5 million/mL in the ejaculate, those with immunological infertility, and those with anatomic problems precluding sperm delivery (such as hypospadias) are candidates for IUI. Men with a total motile sperm concentration of 500,000 to 5 million/mL either surgically retrieved or in the ejaculate are suitable candidates for IVF while those with total motile sperm concentrations below 500,000/mL should consider ICSI, which theoretically requires only one single viable sperm to produce a pregnancy.

For men with iatrogenic OA, vasal reconstruction has been found to be a more cost-effective management strategy than ART, with the value proposition more dependent on female age and fertility potential than on obstructive interval.[79,80] Ultimately, the decision on whether to pursue vasal reconstruction or ART in men postvasectomy will vary with each couple and rely on factors such as female age/fertility potential, desired number of children, and willingness to undergo IVF.

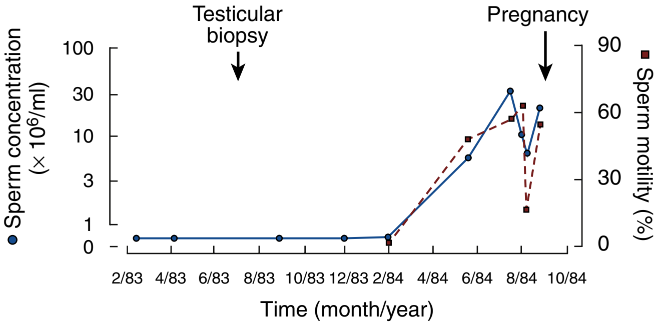

Figure 113.8 **Sperm Concentration and Motility in a Man With Severe Oligospermia and Severe Hypospermatogenesis Included in a Therapeutic Trial of Clomiphene.** Semen quality improved, and his wife conceived. He was given the placebo! (Data from Baker HW: Requirements for controlled therapeutic trials in male infertility, Clin Reprod Fertil 4:13-25, 1986.)

In short, couples in whom the maternal fertility potential is less than 1 year should favor ART while those in whom the maternal fertility potential is greater than 1 year and/or who desire multiple children should favor vasal reconstruction.

Sperm Retrieval

The goal of sperm retrieval is to obtain a maximal amount of viable sperm for use in ART while minimizing the amount of damage to the reproductive tract. Different techniques are available for use in men with OA and for those with NOA (Table 113.7). In men with OA, sperm can be successfully retrieved in almost all patients from the vas deferens via vasal aspirate,[96] from the epididymis via either percutaneous epididymal sperm aspiration (PESA)[97] or microsurgical epididymal sperm aspiration (MESA),[98] and/or from the testicle via either testicular sperm aspiration (TESA) or testicular sperm extraction (TESE).

On the other hand, men with NOA present a much greater challenge, with traditional sperm retrieval rates of only 25% to 50%. Because of the poor sperm production in men with NOA, sperm can often be retrieved only from the testicle. Variations of TESE that have been developed to improve the success rate of sperm retrieval for use in ICSI in men with NOA include microdissection TESE (micro-TESE), in which an operating microscope is used to identify and remove fuller seminiferous tubules within the testicle that are more likely to harbor spermatogenesis (Fig. 113.9).[81] Micro-TESE, which results in the removal of much less testicular tissue than TESE, has resulted in both an improvement in sperm retrieval rates (Table 113.8) and a decrease in complication rates when compared with TESE.[82,99] Other strategies that have been developed include fine-needle aspiration (FNA) mapping, in which multiple diagnostic fine needle aspirations are systematically taken in a bid to create a map of spermatogenesis locations within the testis that can be used to direct future TESA or TESE at the time of ICSI.[83]

CONCLUSION

With male factor contributing to 50% of infertility, the appropriate and concurrent management of the male is critical. While the evaluation of the infertile male aims to identify correctable causes of infertility that can guide therapeutic decision making for the infertile couple, it can also detect significant medical problems related to infertility. The management of male infertility involves a combination of lifestyle, medical, and surgical strategies, but with the advent of ICSI and surgical sperm retrieval techniques, even the most severe male factor infertility can often be successfully overcome.

TABLE 113.7 Summary of Sperm Retrieval Techniques for Men With OA[91–93]

Procedure	Anesthesia	Sperm Retrieval Rate	Advantages	Disadvantages
Vasal aspiration	General/regional	100%	Most mature sperm	Requires delicate microsurgical reconstruction of vasotomy
PESA	Local	80% to 100%	Office procedure Minimal recovery	Hematoma May not retrieve adequate sperm Can induce epididymal obstruction
MESA	General/regional	95% to 100%	High likelihood of obtaining adequate sperm May perform simultaneous reconstruction	Requires operating room and microsurgical skills
TESA	Local	52% to 100%	Office procedure Minimal recovery	Hematoma May not retrieve adequate sperm
TESE	General/regional	100%	Fast procedure No microsurgical skills required	Risk of testicular atrophy and hypofunction Requires operating room More invasive and longer recovery

MESA, Microsurgical epididymal sperm aspiration; *OA,* obstructive azoospermia; *PESA,* percutaneous epididymal sperm aspiration; *TESA,* testicular sperm aspiration; *TESE,* testicular sperm extraction.

Summary and Future Directions, 1914

THE NEED FOR MALE CONTRACEPTION

Globally, the estimated unintended pregnancy rate between the years 1990 and 2014 was 44%. During this same period, a decline in unintended pregnancies of 30% in developed countries and 16% in developing countries was observed.[1,2] Over 50% of unintended pregnancies ended in abortions.[3] The decline in unintended pregnancy is attributable to improvements in reproductive and sexual health services and family planning programs. In addition to the mental, physical, and social impact of unintended pregnancies, the medical costs in the United States are estimated to be $4.5 to $11.1 billion; this cost could be substantially reduced by adherence to modern contraceptive methods.[4,5]

The female partner has traditionally accepted family planning responsibilities, though surveys indicate that both partners make contraceptive choices. Despite the many methods available to women, the failure rate of many types of reversible contraception remains high (Fig. 114.1).[6–9] Effective female hormonal methods include implants and intrauterine devices with typical use failure of less than 1%, whereas higher but acceptable typical use failure rates are observed with injections (6%), daily oral pill, patch, or vaginal rings (9%). Timing-dependent methods such as the female condom, spermicides, sponge, and fertility awareness methods have high failure rates of over 20%. More importantly the adherence rate of female hormonal methods after 12 months is only 50% to 70% with lower adherence in young women and higher adherence with long-acting reversible contraception compared with short-acting methods.[10,11] The adherence rate does not appear to improve with intensive counseling.[12]

In contrast to female methods of contraception, male-controlled methods include coital dependent, reversible methods of withdrawal and condom, and the irreversible method of vas occlusion. Thus there is a need for increasing the options for male contraception to meet the needs of men at different stages of their sexual and reproductive life and to provide them with choices that are not timing dependent yet reversible. The attitudes of men are changing with more men willing to share responsibilities in family planning.[13] According to a pharmacoeconomics study, about 50% of men between the ages of 15 and 64 years may wish to use a male contraceptive, which is equivalent to a potential market of about 44 million men.[14] Thus this is the time to develop and introduce new male contraceptives.[15]

KEY POINTS

- Availability and use of modern family planning methods is a key determinant of unintended pregnancies.
- Many men are willing to share responsibility in family planning; however, few modern methods are available to them.

CURRENT METHODS

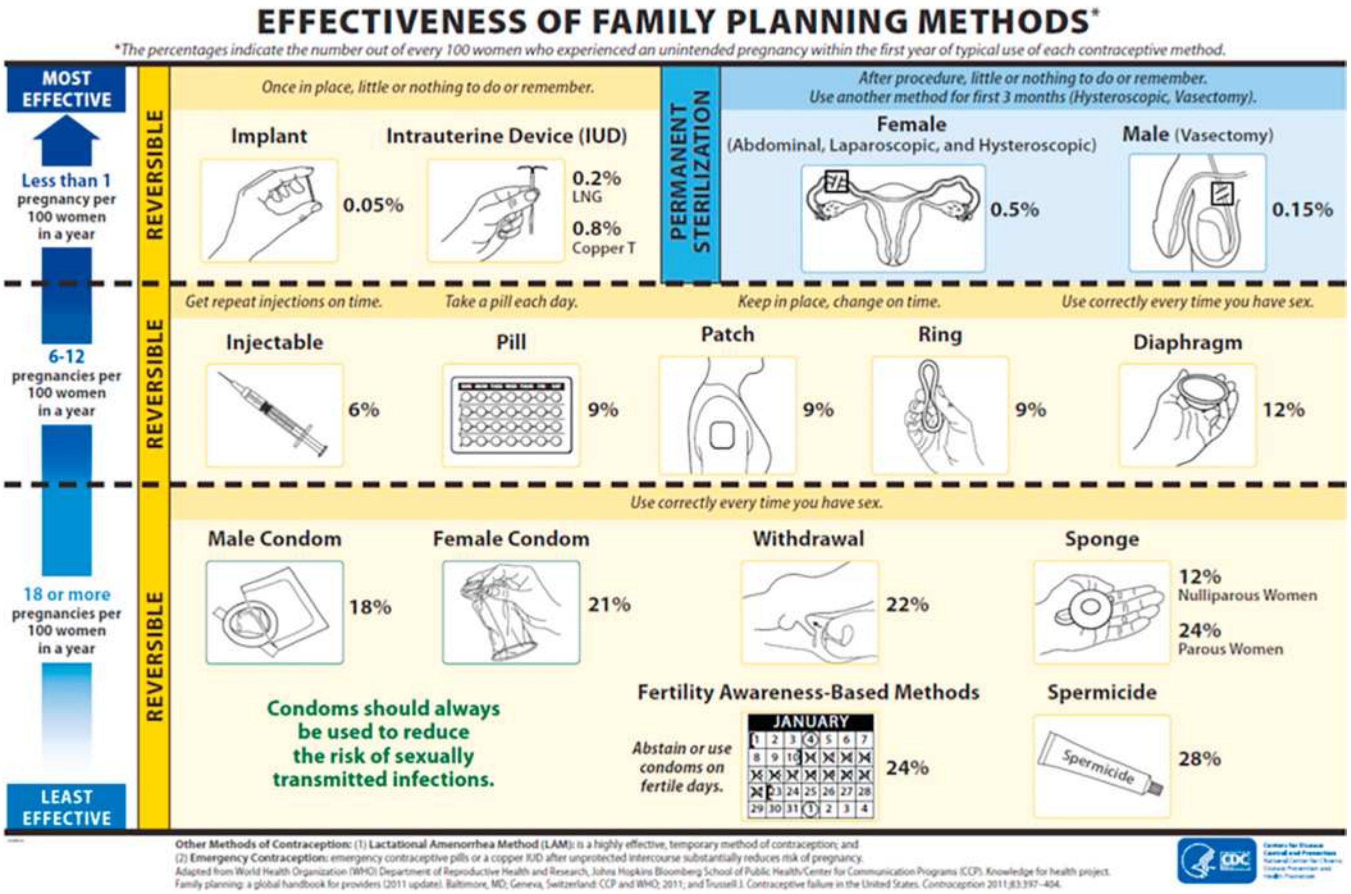
In addition to sexual abstinence, the currently available contraceptive methods for men include withdrawal and condom with high typical use contraceptive failure rates of 22% and 18%, respectively (Fig. 114.1). Though these methods are reversible, they are dependent on the male to correctly and predictably use the method. The alternative available method is vas occlusion, which is considered irreversible because pregnancy rates after vasectomy reversal are low despite patency of the reanastomosis.

Withdrawal

Coitus interruptus or withdrawal requires the user's self-control as the ejaculate with spermatozoa will enter the vagina if withdrawal is not timed before ejaculation. The female partner also must trust that the male can and will withdraw his penis from the vagina before ejaculation. Few studies have been performed on withdrawal.[16] The failure rate is high (22%),[9] but a recent survey study in 43 countries estimated a lower failure rate of 13.4%.[17] Because of the high failure rate, family planning providers should provide emergency contraception for the female partner for couples relying on withdrawal.

Male Condom

The male condom is the most frequently used male method globally at 7.7%. Percentage varies among regions with the highest rate in Europe and lowest in Africa.[13] In the United States, the prevalence of condom use in men aged 15 to 44 years is 33.7%, but only about one-third use condoms all the time.[18] Condoms when used appropriately provide a barrier between the penis, the seminal fluid containing spermatozoa, and the vagina. The added value of condoms is prevention of sexually transmitted infections including the human immunodeficiency virus,



EFFECTIVENESS OF FAMILY PLANNING METHODS*
*The percentages indicate the number out of every 100 women who experienced an unintended pregnancy within the first year of typical use of each contraceptive method.
MOST EFFECTIVE
Less than 1 pregnancy per 100 women in a year
6-12 pregnancies per 100 women in a year
18 or more pregnancies per 100 women in a year
LEAST EFFECTIVE
REVERSIBLE
Once in place, little or nothing to do or remember.
Implant
0.05%
Intrauterine Device (IUD)
0.2% LNG
0.8% Copper T
PERMANENT STERILIZATION
After procedure, little or nothing to do or remember.
Use another method for first 3 months (Hysteroscopic, Vasectomy).
Female (Abdominal, Laparoscopic, and Hysteroscopic)
0.5%
Male (Vasectomy)
0.15%
Get repeat injections on time.
Take a pill each day.
Keep in place, change on time.
Use correctly every time you have sex.
Injectable
6%
Pill
9%
Patch
9%
Ring
9%
Diaphragm
12%
Use correctly every time you have sex.
Male Condom
18%
Female Condom
21%
Withdrawal
22%
Sponge
12% Nulliparous Women
24% Parous Women
Condoms should always be used to reduce the risk of sexually transmitted infections.
Fertility Awareness-Based Methods
Abstain or use condoms on fertile days.
JANUARY
24%
Spermicide
28%
Other Methods of Contraception: (1) Lactational Amenorrhea Method (LAM): is a highly effective, temporary method of contraception; and
(2) Emergency Contraception: emergency contraceptive pills or a copper IUD after unprotected intercourse substantially reduces risk of pregnancy.

CDC

Figure 114.1 Effectiveness of family planning methods. This figure shows the most effective currently available method from the top to the least effective at the bottom. The percentage is the Pearl index that is the number of unintended pregnancies per 100 women within the first year of typical use of the method. Male method includes vasectomy with a failure rate of 0.15% to condom of 18% and withdrawal of 22%. (From *Centers for Disease Control and Prevention,* How effective are birth control methods? https://www.cdc.gov/reproductivehealth/unintendedpregnancy/pdf/family-planning-methods-2014.pdf.)

herpes simplex virus, gonorrhea, chlamydia, and syphilis.[19] Thus condoms are frequently used by single men during casual sexual encounters.

The success of condom use depends on the correct application of the condom on the erect penis and removal of the condom after intercourse.[20] It is important that family planning providers counsel the user on the correct application and disposal of the condom.[21] The typical use failure rate of condom is estimated to be 18%,[9] but recent evidence suggests that the failure rate is lower at 12.6%.[22] The common causes of contraceptive failure of condoms reported by women seeking abortions are inconsistent use and breakage or slippage of the condom.[23] Condoms are usually made of latex and nonlatex condoms are made of polyurethane for individuals who are sensitive to latex. Compared with latex condoms, polyurethane condoms have higher breakage rates.[24] Natural membrane condoms are not recommended because of the high breakage rates.

KEY POINTS

- Current reversible male contraceptive methods are timing dependent and have a high typical use failure rate.
- Withdrawal during coitus requires the male user's self-control and understanding.
- Condom success in pregnancy prevention depends on the correct application at the right time.

Vas Occlusion

Vas occlusion shows a large difference in acceptability by couples from different geographical areas; higher prevalence (12% to 19%) has been reported from Australia, Bhutan, Canada, The Netherlands, New Zealand, Korea, United Kingdom, and United States, compared with very low use in Africa (0.1%), Central and South America (2%).[25] The number of couples relying on vasectomy as a contraceptive method has remained relatively constant since the 1990s. Vasectomy prevalence is about 6.6% in men aged between 18 and 45 years in the United States and is higher in Whites, older age, nonimmigrants, and those with higher income and education.[26] There has been a suggested link between vasectomy and an increased risk of prostate cancer but this has been refuted by epidemiological studies.[27,28]

The current recommended method of vas occlusion is performed under local anesthesia, using a "no-scalpel vasectomy" or other minimally invasive techniques.[29] The ends of the vas should be closed with cautery with fascial interposition or by ligature or clips. The success of vas occlusion is determined by postvasectomy semen analyses. The couple should use another method of contraception until semen samples showed azoospermia or rare nonmotile sperm concentration (<100,000 nonmotile sperm). It takes from 8 to 16 weeks to reach this very low nonmotile sperm concentration in the ejaculate. The failure rate of vasectomy is rare (<1%).[30] If after 6 months, azoospermia or near azoospermia is not reached, repeat vasectomy should be considered. With minimally invasive surgery, postoperative complications are very few, about 1% to 2% including hematoma and infection. Few men (1% to 2%) developed chronic scrotal pain after vasectomy that rarely impairs quality of life.[30]

Men are generally satisfied with vas occlusion and accept this as a permanent method of contraception. Counseling men and the couple before vasectomy increases postvasectomy satisfaction.[31] Reversibility of vasectomy can be achieved by vasovasostomy or vasoepididymostomy. Although the patency after surgery is about 87%, the pregnancy rate in the partner is only about 49%. Factors that adversely affect the success of reversal and pregnancy include a longer interval between vasectomy and reversal, older age of female partner, and small testicular volume. Presence of sperm and a sperm granuloma is indicative of higher success in reversal and pregnancy.[32]

There are new developments in vas occlusion methods to gear toward enabling reversibility. RISUG,[33] Adam, and Vasalgel are in development. These methods inject vas occlusion material into the vas deferens to block sperm transport with the notion that the material can be flushed or removed when men desire reversal. The intravas injection of Vasalgel proved to be an effective contraception in rhesus monkeys, though one out of nine monkeys had incorrect placement of gel and development of a sperm granuloma in another.[34] Clinical trials demonstrating reversal of these novel vas occlusive methods have not yet been reported.[35,36]

KEY POINTS

- Vas occlusion is an effective permanent method of contraception with few complications and acceptability by users.
- Reversal leads to patency in a high proportion of men but pregnancy rate is much lower in the partner.
- New methods of vas occlusion are in development to make vas occlusion more reversible.

MALE-DIRECTED CONTRACEPTIVE METHODS IN DEVELOPMENT

Hormonal Male Contraception

Since the 1970s, investigation of hormonal male contraception has been spearheaded by the Eunice Shriver National Institute of Child Health and Human Development (NICHD).[37] The NICHD initiated studies using the testosterone ester (testosterone enanthate) as the sole agent for hormonal male contraception given its ability to suppress gonadotropin secretion and to maintain androgenicity in men.[38–40] There is a quest for a reversible method of male contraception based on sex hormones used for the treatment of male hypogonadism and on hormonal methods for the female.

Principles of Hormonal Contraception. Hormonal male contraception depends on negative feedback mechanisms in the endocrine system wherein the target organ hormone, testosterone, restrains the secretions of regulatory hormones from the hypothalamus and pituitary. In the male, the hypothalamic hormone gonadotropin-releasing hormone (GnRH) stimulates the pituitary to produce two hormones: luteinizing hormone (LH) that stimulates the Leydig cell in the testis to produce testosterone and follicle-stimulating hormone (FSH) that acts on the Sertoli cell to support spermatogenesis (Fig. 114.2). The high intratesticular concentration of testosterone is essential for germ cell development into mature spermatozoa. Knockout of the androgen receptors in the Sertoli cells of the testis in mice results in arrest of spermatogenesis at the primary spermatocytes, whereas knockout of androgen receptor in Leydig cells results in disruption of steroidogenesis, testosterone deficiency, and arrest of spermatogenesis at the round spermatid stage.[41] These studies show the critical role of testosterone within the testis for progression of spermatogenesis.

Hormonal male contraception utilizes exogenous administration of an androgen or an androgen plus a progestin or a GnRH agonist/antagonist with the goal of maximally suppressing both LH and FSH. This results in marked decrease in intratesticular testosterone production, but the exogenously administered androgen maintains sexual function and the important effects of androgens on the muscle, bone, and erythropoiesis. The serum concentrations of testosterone attained are within the physiological range, maintaining androgen action in the body, but are insufficient to maintain spermatogenesis.[42] The low intratesticular testosterone results in arrest of the development of spermatogenesis mainly at the differentiated spermatogonia and primary spermatocytes.[43] Upon discontinuation of the exogenous hormones, the hypothalamic-pituitary suppression rebounds, leading to increased intratesticular testosterone production and gradual recovery of spermatogenesis from undifferentiated spermatogonia (Fig. 114.2).[44,45] All hormonal male contraceptives will need testosterone or an androgen to maintain androgenic effects in men.

It takes about 74 days to complete the development of spermatogonia to mature spermatozoa.[46] Therefore hormonal male contraception that relies on the suppression of spermatogenesis takes an average of 60 to 90 days to produce very low sperm output and about the same time for recovery to full spermatogenesis. An integrated analysis of 30 male hormonal contraceptive clinical trials in over 1500 men showed that the probability of recovery to a sperm concentration within the reference range of fertile men was 67% in 6 months, 90% in 12 months, and 100% in 24 months. Recovery rate was higher in older men, men of Asian origin, those with shorter treatment duration, treated with short-acting testosterone preparations, higher baseline sperm concentration, faster spermatogenesis suppression, and lower serum LH at baseline.[47] Thus hormonal male methods are reversible. Because hormones act on many tissues of the body, male hormonal contraceptives may have beneficial off-target effects (e.g., increase in muscle, bone mass, and maintenance of erythropoiesis). The full implications of long-term effects on lipids, cardiovascular disease risks, and prostate diseases will not be known until hormonal male contraception is available for use and long-term large-scale epidemiological studies are performed as has been done for the female hormonal methods.[44] The androgens and progestins that have been tested in clinical trials in men are shown in Table 114.1.

Androgens. Testosterone enanthate and undecanoate intramuscular injections, testosterone implants, oral testosterone undecanoate, testosterone patch, and gel have been used in hormonal male contraceptive trials where suppression of spermatogenesis was the primary outcome.[44,45] Oral testosterone undecanoate had inadequate suppression of gonadotropins and spermatogenesis.[48] Based on the promising studies showing that testosterone enanthate administered as intramuscular injections resulted in suppression of spermatogenesis to azoospermia (no sperm detected in the ejaculate) or severe oligozoospermia (arbitrarily defined as <5 million/mL),[38–40] the World Health Organization (WHO) designed two consecutive studies that administered testosterone enanthate intramuscular injections (200 mg once per week) to healthy male volunteers for 1 year. The primary outcome was the prevention of pregnancy in the female partner when the sperm concentration is suppressed to azoospermia in the first study,[49] and to severe oligozoospermia in the second study[50] (Table 114.2). As in all hormonal male contraceptive studies, the efficacy studies recruit couples after screening and require male participants to reach a sperm

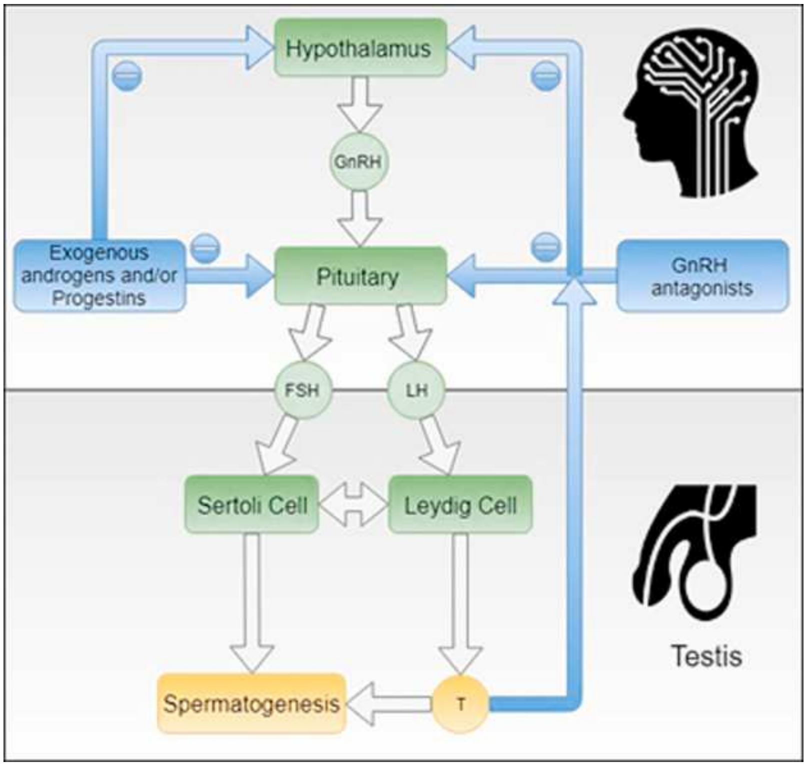

Figure 114.2 Principles of hormonal male contraception. Exogenously administered androgens and/or progestins exert negative feedback on the hypothalamic-pituitary reducing the secretion of gonadotropin-releasing hormone *(GnRH)* from the hypothalamus and both luteinizing hormone *(LH)* and follicle-stimulating hormone *(FSH)* from the pituitary. GnRH antagonists compete with the action of endogenous GnRH on the pituitary and inhibit the section of both gonadotropins. LH regulates the secretion of testosterone *(T)* by the Leydig cells and FSH regulates the function of the Sertoli cells. Inhibition of LH secretion results in very low concentration of intratesticular T, which is critical for initiation, and maintenance of spermatogenesis. Concomitant reduction of FSH further inhibits progression of spermatogenesis. Despite the marked suppression of endogenous T production by Leydig cells, prevention of testosterone deficiency and maintenance of androgen effects are provided by the exogenously administered testosterone or another androgen that is an essential component of hormonal male contraception. concentration threshold in two or three samples in the suppression phase, initially defined as ≤5, then reduced to ≤3, and finally to ≤1 million/mL ejaculate based on expert opinion and available data.[51] Then the couple would enter the efficacy phase where they will use the method under investigation as the sole method of contraception. Recovery is defined when the sperm concentration returns to values compatible with fertility in a male. The WHO studies showed that testosterone enanthate weekly injections were efficient at inducing azoospermia in about 70% of men after 6 months and severe oligozoospermia or azoospermia in almost all men (97.8%). These two studies indicated that hormonal male contraception using androgen alone was very effective in preventing pregnancy. Because the dosage of testosterone injections in these two studies was high (approximately twice the normal physiologic production of testosterone in healthy men) and required weekly injections, subsequent studies sought to administer testosterone implants[52] or testosterone undecanoate injections[53,54] that had a longer duration of action. The contraceptive efficacy of these studies (Table 114.2) confirmed that testosterone injections and implants were as efficacious as injectable used for hormonal female contraception and much better than condom or withdrawal (Fig. 114.1). The adverse effects reported by men participating in these clinical trials were anticipated, including increased acne, oiliness of skin, mild weight and hematocrit increases, and small decreases in high-density

lipoprotein-cholesterol levels. These side effects did not cause early discontinuations.[55] The dosages of androgens used in these studies may be considered higher than dosages used for testosterone replacement in hypogonadal men. Furthermore, the suppression of sperm output showed an ethnic/racial difference in that the suppression to severe oligozoospermia or azoospermia was higher in Asian (>90%) versus non-Asian men (~60% to 70%).[49,50,56] For these reasons, clinical trials began utilizing an additional gonadotropin-suppressing agent, a progestin, or a GnRH agonist or antagonist, together with a male hormone to suppress spermatogenesis.

Androgens and Progestins. The addition of a progestin to testosterone in hormonal male contraceptive clinical trials more effectively suppresses the hypothalamic–pituitary–testis axis. It is believed that this combined hormonal approach will allow use of reduced dosages of testosterone to physiological concentrations with retained efficacy by the combined treatment. This remains under study, as the use of two agents instead of testosterone alone adds complexity in regulatory development and requires more data on the safety of the progestin in men. Despite these caveats, many progestins have been tested in male contraceptive clinical trials. Levonorgestrel, desogestrel, and cyproterone acetate oral pills, intramuscular depot-medroxyprogesterone acetate (DMPA) and norethisterone enanthate injections, and levonorgestrel and etonogestrel implants have been studied and transdermal nestorone (NES-T) gel is currently being studied. These progestins have been used in combination with oral testosterone undecanoate, testosterone enanthate, decanoate, and undecanoate injections, testosterone implants, and transdermal testosterone gel (Table 114.1).[44,57] In spermatogenesis suppression studies with small numbers of men, these combinations of testosterone injections or implants plus progestin oral preparations, injections, implants, and gel have effectively suppressed sperm output to azoospermia and/or very severe oligozoospermia in over 95% of men. In addition to improved suppression of sperm output, the combined androgen-progestin regimens appear to suppress spermatogenesis faster than androgens alone.[58]

Two contraceptive efficacy studies with testosterone plus a progestin have been reported (Table 114.3). Testosterone 800 mg implants every 4 to 6 months together with intramuscular DMPA 300 mg every 12 weeks suppressed sperm concentration to ≤1 million/mL in over 94% of men and prevented pregnancy in their female partners.[59] In a larger study, 1000 mg of testosterone undecanoate was administered with 200 mg norethisterone enanthate as intramuscular injections every 8 weeks to 320 couples. Results showed 95.9% of men suppressed to a sperm concentration ≤1 million/mL (the threshold for contraceptive efficacy) and only four pregnancies occurred in 266 couples giving a failure rate of 1.57 per 100 continuing users (Table 114.3).[60] The common adverse events were pain at the injection site, acne, increased libido, and mood changes. Most of the adverse events were mild and concentrated at one clinical study site, but an external safety review committee prematurely stopped the study because of mood disorders including depression. Some of the adverse events may be related to low serum testosterone levels at the end of the injection interval and the different pharmacokinetics of testosterone undecanoate and norethisterone enanthate. Moreover, the participants were not screened for depressive symptoms and prospective monitoring of mood and sexual function was not included in the study. Despite these adverse events, the male participants expressed a high level of satisfaction and over 87% of both male and female participants affirmed they would use this as a method of contraception if available.[60] While other long-acting reversible male contraception regimens are being developed, user-friendly, provider-independent methods of drug delivery are under investigation. Daily transdermal application of testosterone gel together with a potent novel progestin without androgenic and estrogenic activity, Nestorone (segesterone acetate), was shown to be more effective in suppressing gonadotropins and spermatogenesis than testosterone gel alone in men. Minimal adverse events were reported.[61,62] Currently, a contraceptive efficacy study of transdermal testosterone and Nestorone gel with a plan of recruiting 420 couples with over 50% of them completing 12 months of the efficacy phase is ongoing in 13 centers in four continents.

KEY POINTS

- Addition of a progestin to testosterone suppresses spermatogenesis faster than testosterone alone.
- Oral pills, transdermal gel, injections, and implants of various progestins have been combined with testosterone injection, implants, and transdermal gels in male contraceptive clinical trials.
- Contraceptive efficacy studies with progestins combined with injections or implants of testosterone result in severe oligozoospermia in most men and prevention of pregnancy rates in couples approximating efficacy as for hormonal female methods.

Gonadotropin-Releasing Hormone Agonist and Antagonists. Both GnRH agonists and antagonists in combination with testosterone injections have undergone clinical trials in men. GnRH agonists initially induce increases in both LH and FSH but then owing to downregulation of the gonadotropin receptors result in marked suppression of both gonadotropins and testosterone production. These agents have been widely used in androgen depletion therapy for prostate cancer and for precocious puberty. However, GnRH agonists' injection or infusion together with testosterone injections failed to suppress sperm output to severe oligozoospermia in most men.[63,64] In contrast, GnRH antagonists administered as a subcutaneous daily injection together with testosterone supplementation were efficacious in suppressing sperm output to azoospermia or severe oligozoospermia in most men.[65–68] It was also demonstrated that once sperm suppression was induced by the GnRH antagonist plus testosterone enanthate injections, azoospermia could be maintained for 6 months with replacement dosages of testosterone enanthate alone.[69] Despite the success with GnRH antagonists, the cost of production and the requirement of daily injections impeded the further development of these agents as viable hormonal male contraceptives. Oral bioavailable GnRH antagonists are being developed for the treatment of endometriosis and uterine fibroids.[70,71] Such agents could be tested in clinical trials in men combined with new orally bioavailable testosterone undecanoate preparations that sufficiently raise testosterone levels to the adult range in hypogonadal men.[72]

Other New Hormonal Agents for Male Contraception

A modified androgen 7-α methyl 19-nortestosterone (MENT) formulated as an implant showed promise as a possible male contraceptive agent.[73] However, the release of testosterone was not maintained in all batches of MENT implants[74] and the redevelopment of the implant is in progress. Novel-modified androgens related to MENT that bind to and activate both the androgen and progesterone receptors have the potential of one compound possessing the effects of two steroids and may mimic the action of combined androgen and progestins regimens. These include dimethandrolone (DMA, 7α,11β-dimethyl-19-nortestosterone) and 11β-MNT (11β-methyl-19-nortestosterone) administered as prodrugs DMA undecanoate (DMAU)[75,76] and 11β-MNT dodecylcarbonate (11β-MNTDC).[77] In contrast to 19-nortestosterone, the backbone of these modified androgens, these compounds are not aromatized to estrogenic compounds and are not subjected to 5α-reductase activity, resulting in less prostate-stimulating activity. Both compounds have been administered to healthy men as a daily oral pill with marked suppression of LH, FSH, and testosterone while maintaining sexual and other androgenic functions.[44,77] Both DMAU and 11β-MNTDC are being developed not only as oral pills but also as intramuscular injections as potential male contraceptives.

KEY POINTS

- GnRH antagonists are very effective suppressors of the hypothalamic–pituitary–testis axis and when administered with testosterone suppresses sperm concentration to very low levels compatible with contraceptive efficacy. New orally bioavailable agents are being developed.
- New orally bioavailable androgens with progestational activity are being tested in clinical trials to assess whether these agents can suppress spermatogenesis.

Nonhormonal Targets for Male Contraception

Since hormones act on many other biological systems other than the hypothalamic–pituitary–testis axis, off-target effects can occur. Nonhormonal agents acting on a specific cellular protein or biological process in the male reproductive tract mainly exert localized effects for inhibiting sperm production, motility, or fertilizing capacity. The common approach to nonhormonal male contraceptive development is to identify a target (usually a protein with expression mostly restricted to the male reproductive tract); to demonstrate regulation/disruption of the target gene leads to infertility; and demonstration that the target is druggable (i.e., proteins with binding niches where small-molecule inhibitors can bind). Once the target is identified, drug development usually requires screening for small molecules that bind to the target scaffold using high-throughput screening with measurable readouts. Alternatively, new targets can be discovered by integrating human and mouse RNA-seq datasets combined with additional analyses of human and mouse testis and epididymis.[78] Targets include spermatogenesis, spermiogenesis, sperm maturation in the epididymis, sperm motility, hyperactivated sperm motility, capacitation, acrosome reaction, binding to the zona pellucida, and sperm–egg fusion (Fig. 114.3).[79–81] Examples of a few nonhormonal targets are discussed.

Spermatogenesis as a Target. Hormonal methods act on spermatogenesis with arrest of spermatogenesis at the differentiating spermatogonia. Retinoic acid receptor α (RARα) is required for spermatogenesis.[82] Antagonists to RARα induce reversible inhibition of spermatogenesis and infertility in mice.[83] Structure-activity-based drug design may yield small molecules that will prevent binding of RA to RARα, specifically inhibiting spermatogenesis. Another approach is to disrupt the synthesis of RA using bisdichloroacetyldiamine (BDAD), which leads to spermatogenesis suppression in men.[84] Unfortunately, BDAD causes a severe disulfiram reaction after alcohol consumption

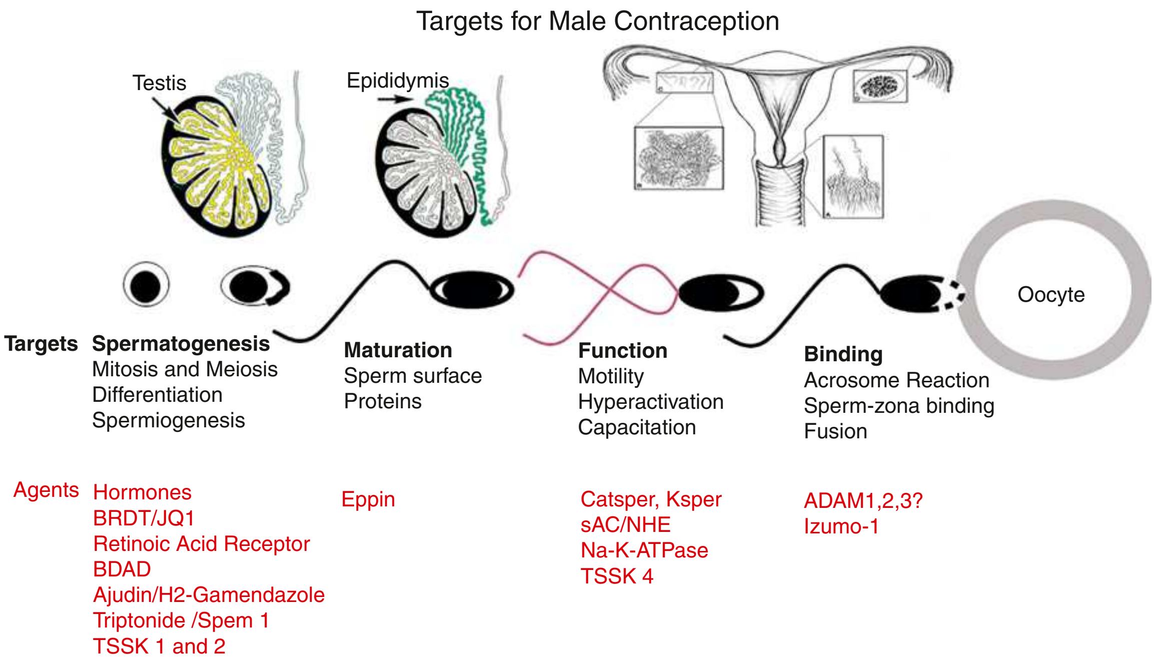

Figure 114.3 Targets for male contraception. The targets for male contraception include processes in sperm development (spermatogenesis and spermiogenesis in the testis), maturation, acquisition of motility (transit through the epididymis), and the ability to hyperactivate, undergo acrosome reaction, and bind and fuse with oocyte. Possible contraceptive agents include those that act in the *testis* and affect *spermatogenesis*: Retinoic acid receptor (RARα) antagonist, bisdichloroacetyldiamine (BDAD), bromodomain testis-specific protein (BRDT); *tight junctions* between Sertoli and germ cells: Adjudin and H2-gamendazole; *spermiogenesis*: Spermatid maturation 1 (Spem1) and testis-specific serine kinase protein (TSSK 1 and 2). In the *epididymis*, where *sperm maturation and acquisition of motility* occurs, epididymal protease inhibitor (EPPIN) antibodies and antagonist reduce sperm motility and cause infertility. In the *female reproductive trac*t, agents that affect *sperm motility and hyperactivated motility*: ion channels CatSper and KSper; soluble adenylyl cyclase sAC and sodium-hydrogen exchangers (NHE), sodium-potassium ATPase (Na-K-ATPase) and testis-specific serine kinase 4 (TSSK4); *sperm transport and fertilization*: a disintegrin and metalloproteases (ADAMs) family proteins ADAM 1a, 2, and 3; IZUMO1 and JUNO. (Adapted from Gottwald U, Davies B, Fritsch M, Habenicht UF. New approaches for male fertility control: HE6 as an example of a putative target. *Mol Cell Endocrinol*. 2006;250(1-2):49-57.)

due to the inhibition of aldehyde dehydrogenase 2 resulting in aldehyde intoxication.[85] Studies are currently underway to custom design and synthesize an inhibitor of the testis-specific aldehyde dehydrogenase 1A2 enzyme to avoid the disulfiram reaction while retaining the intratesticular effect of BDAD on spermatogenesis.

Bromodomain testis-specific protein (BRDT) knockout mice are infertile. A small-molecule inhibitor (JQ1) of BRDT causes reversible suppression of spermatogenesis in mice. BRDT is essential for chromatin remodeling during spermatogenesis. Current efforts are directed to screen molecules based on structure-activity relationships for new testis-specific compounds.[86] A number of indazole carboxylic acid compounds disrupt junctions between Sertoli and male germ cells causing immature germ cell loss from the seminiferous epithelium.[87] These compounds, including adjudin[88,89] and H2-gamendazole,[90] induce reversible infertility in rodents. Unfortunately, these compounds have little penetrance across the blood–testis barrier, raising a concern for irreversible effects with high cumulative dosages.

Spermiogenesis as a Target. Spermiogenesis is the process whereby postmeiotic haploid round cells develop into elongated spermatids and spermatozoa with the sperm head containing the nucleus and the acrosome, the mid-piece with mitochondria and the flagellum. Spermiogenesis genes are testis specific and are conserved.[91] Gene knockouts of Spermatid maturation 1 (*Spem1*)[92] and Spermatogenesis-associated Protein 6 (*Spata6*)[93] affect late spermiogenesis and result in mice with normal testicular histology but with malformed spermatozoa that are not capable of demonstrating forward progressive motility. A recent study reported that triptonide, purified from *Tripterygium wilfordii*, when administered to mice and monkeys caused deformed sperm and infertility. Triptonide appeared to disrupt the interaction of the junction plakoglobin with SPEM1.[94] Testis-specific serine kinase (TSSK) 1 and 2 are critical for spermiogenesis and double-knockout mice show sperm head abnormalities and are infertile. TSK6 knockout mice showed altered head morphology and impairment attachment of the sperm head to the mid-piece due to defects in sperm DNA condensation, chromatin remodeling, and histone to protamine transition.[95] The hope is to use high-throughput small-molecule screening to identify specific molecules that target these crucial gene products and thus reversibly impair spermiogenesis.

Sperm Maturation and Sperm Motility as Targets. While transiting through the epididymis, spermatozoa acquire many sperm surface proteins essential for sperm maturation, acquisition of motility, and development of fertilizing capacity. Thus epididymal[96] and sperm motility signaling pathway proteins[97] are potential targets of male contraception. The sperm surface protein, epididymal protease inhibitor (EPPIN), is important for forward progressive motility of spermatozoa. Antibodies to EPPIN and a specific inhibitor of EPPIN (EP055) reduced sperm motility and caused infertility in rodents and monkeys.[98,99]

Ion channel proteins are produced in the tail end of the flagellum and control the calcium influx. Hyperactivated motility is activated through voltage-gated ion channels CatSper (calcium ion channel) and KSper (potassium ion channel). Hyperactivated motility is necessary for spermatozoa transit through the female reproductive tract and penetration of the zona pellucida. The structure and dynamics of these ion channels are very complex. CatSper is regulated by progesterone, intracellular pH, and endocannabinoids. CatSper deficient mice and men with certain CatSper gene mutations are infertile. Spermatozoa deficient in CatSper fail to fertilize an oocyte and those deficient in KSper can fertilize but at a markedly reduced rate.[100] Because CatSper is sperm specific and affects hyperactivated motility in the female reproductive tract, small molecule targeting the channel subunits may be developed as both male and female nonhormonal contraceptives.[101]

Other potential target is the soluble adenylyl cyclase. Disruption of this enzyme results in loss of sperm motility and infertility in mice.[102] The Na-H exchanger (NHE) is critical for the regulation of adenylyl cyclase and sperm motility.[103] In addition, loss of NHE 8 disrupts acrosome formation and causes infertility.[104] The Na-K ATPase (NKA) catalytic subunit NKAα4 (ATP1A4) is testis specific, present in spermatozoa, and required for sperm motility. This catalytic subunit is being used as a target to block ion transport and disrupt male fertility.[105] TSSK4 knockout mice have decreased sperm motility because of abnormality of the annulus at the principle and mid-piece junction resulting in bent flagellum.[95] Current research focuses on the development of cell membrane permeable inhibitors that are druggable.

Sperm Transport and Sperm–Egg Binding and Interaction. Based on gene knockout studies in mice, many gene products have been reported to impair sperm function and sperm–egg interactions. A family of disintegrins and metalloproteases (ADAMs), ADAM 1a, 2, and 3 are important in mouse sperm migration through the uterotubal junction. ADAM 1a/2 and ADAM 3 are important in inducing the ability of mouse spermatozoa to bind to the zona pellucida. However, the role of ADAM 3 in human fertilization is not clear. Many other gene products may also be required for sperm–egg interaction.[106] More recently, the sperm membrane protein IZUMO1 binding to its receptor JUNO on the oocyte has been identified to be critical for fertilization.[107,108] IZUMO-I-JUNO complex is a target of contraception. Because sperm transport, the acrosome reaction, and sperm–egg binding occur mainly in the female reproductive tract, these are also targets for nonhormonal female methods of contraception as drug delivery to the female reproductive tract may be more streamline for such a method.

KEY POINTS

- Nonhormonal methods target specific gene products essential for spermatogenesis, spermiogenesis, sperm maturation, sperm motility, sperm hyperactivated motility, and sperm–egg binding.
- Drug development involves screening of small molecules or structure-activity-based synthesis of compounds that specifically target a gene product that is critical for fertility.
- Some of the inhibitors are available for testing in rodents and nonhuman primates but none has reached clinical testing in men.
- Unanticipated off-target effects are unknown and require extensive preclinical testing.

Men’s Attitude and Acceptability of Male Contraception

The attitude of men toward family planning responsibility seems to have changed in the last decade. Advancements in the understanding of male reproduction stimulate new developments in male contraception. Gender equity and social justice concepts propel men to acknowledge and accept that family planning and contraceptive use should be shared between the partners.[109,110] The question of whether men will use contraception was examined by multicenter surveys conducted over a decade ago. In a study where over 9000 men in nine countries in four continents were surveyed by phone, 55% to 81.3% of the couples responded that the method of contraception was decided together by the couple. The overall acceptability of a hypothetical, reversible male contraceptive method was 55%, varying between countries.[111] In another multicenter study of over 1800 couples in four countries in three continents, 44% to 83% of the men would use a new contraceptive especially if this was a pill.[112] In this survey, when 1894 female partners were asked, 83% of the women indicated that a new male contraceptive method was a good idea and only 2% of the women would not trust their partner to use the male method.[113] Surveys on men who were participating in clinical trials consistently show that over half of the trial participants will use the method when available, methods that have included injections, transdermal gels, and daily oral pills.[114–117] In an ongoing contraceptive clinical trial of daily NES-T transdermal gel, comprehensive acceptability questionnaires are being collected while in-depth interviews of the couples will be conducted to determine the attitudes and behavior of men and women who are interested and elected to participate in the contraceptive efficacy study that lasts over 18 months.

With social media penetrating the everyday life of younger adults, contraceptive dialogues with online audiences suggest that male contraception is a topic of interest in couples of the reproductive age.[44] Before launching a new male contraceptive method, landscape studies in different countries on different racial/ethnic, socioeconomic groups must be planned to allow the community to inform the researchers what are the best methods to disseminate information and launch new male contraceptive methods.

KEY POINTS

- Multicountry surveys performed a decade ago indicate that over 50% of men would accept a new male-controlled method of contraception.
- Over 95% of women in stable relationship will trust their male partner to use the new male method when available.
- With gender equity, men are willing to accept family planning responsibility.

SUMMARY AND FUTURE DIRECTIONS

The demand for new, modern, reversible methods of male contraception independent of timing of sexual activity will drive the development and approval of a new method of male contraception. There are many possible candidate approaches in the pipeline. As an example, this could be a reversible vas occlusion or a hormonal method. Large-scale studies will need to be performed to demonstrate safety and reversibility of these methods. Launch of new methods must be preceded by landscape studies to optimize dissemination of information surrounding these methods and engage men and couples in male contraceptive utilization. With progress in our understanding of the molecular and cellular processes regulating spermatogenesis, sperm maturation, and acquisition of motility and fertilizing potential of spermatozoa, new testis-/spermatozoa-specific targets are being identified. Using new molecular technologies and high-throughput screening of small molecules that inhibit the critical targets affecting development, maturation, and acquisition of essential functions of spermatozoa, new agents with specific actions on the testis, epididymis, or reproductive tract will be identified. Novel nonhormonal agents will need to pass preclinical toxicology to insure there are no significant off-target adverse effects. Novel male contraceptive agents will preferably induce reversible contraception to expand the contraceptive options for men and couples. Lastly, minimizing the cost of novel male contraceptive methods is of great importance in ensuring these agents have an impact on unplanned pregnancy rates. Only if they are affordable methods for all men, irrespective of their income, will novel male contraceptives realize their potential to have a major impact on global public health.

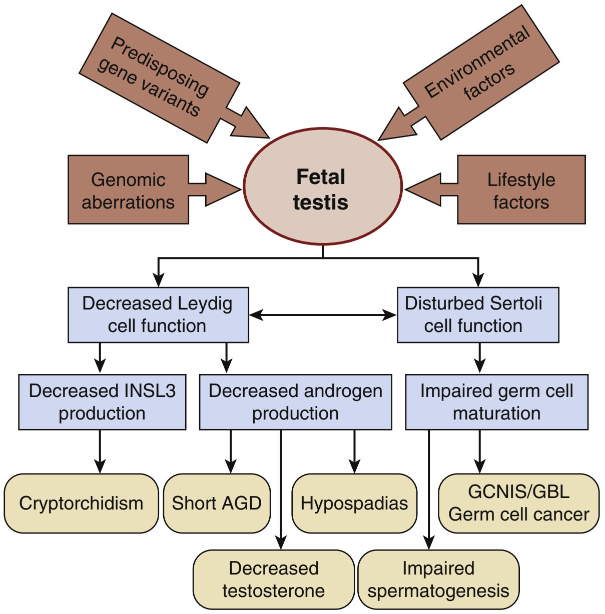
TESTICULAR DYSGENESIS SYNDROME

There is growing evidence that a range of male reproductive disorders diagnosed in children and adults, including cryptorchidism, some forms of hypospadias, testicular germ cell tumors (TGCT) of young adults, and some forms of decreased spermatogenesis—with smaller testis volume and poor semen quality—are linked with disturbed fetal testicular development. Clinical and epidemiological observations in patients with these disorders, combined with biological evidence—especially from studies of preinvasive TGCT—led to the concept of a testicular dysgenesis syndrome (TDS).[1,2] The initial TDS concept has been subsequently enlarged to include additional discrete manifestations of testicular dysgenesis, such as shortened anogenital distance (AGD) and low testosterone levels (adult hypogonadism), as presented in Fig. 115.1. It is important to underline that the main concept of the TDS hypothesis is the predominantly environmental-/lifestyle-related etiology of the syndrome, demonstrated by the changing incidences of its components. On the other hand, TDS prevalence and severity are undoubtedly modulated by the genetic background. Hence, more severe TDS manifestations, especially if present together in one patient (e.g., severe hypospadias and cryptorchidism), overlap with disorders of sex development (DSD).[3] The complexity of the syndrome and its multifactorial pathogenesis led to discussion in the scientific literature, with some authors casting doubt on the existence of TDS but also acknowledging that the TDS hypothesis contributed to stimulating research on the apparently increasing problems in male reproductive health.[4] Even if the existence of the syndrome as one entity can be discussed, a general link between testicular developmental disorders and postpubertal reproductive problems has been proven beyond doubt (reviewed in[2,5]). The epidemiological and biological evidence supporting the concept of TDS is briefly reviewed later.

Further in this chapter, the individual TDS-related disorders are reviewed in detail, including the recently added mild manifestations and possible influence on hormonal changes in male minipuberty. Regarding testicular cancer, only TGCT derived from germ cell neoplasia *in situ* (GCNIS) are considered a part of TDS. However, other testicular tumors, including childhood germ cell tumors and tumors derived from somatic cells (sex cord stromal tumors), are also described in this chapter because of their frequent endocrine manifestations.

Epidemiology

Epidemiological studies of male reproductive disorders have intensified in recent decades, partly in response to a dramatic rise in the incidence of testicular cancer in many countries and partly because of the TDS hypothesis and an increased attention given to reports of the declining semen quality. The adverse trends in testis cancer incidence coinciding with declining semen quality were first reported in Nordic countries, and the suggestion was made that increasing testis cancer rates in a population can be a warning sign of other reproductive health problems in the same area.[2] Positive correlations between the incidence of testicular cancer and hypospadias and between hypospadias and cryptorchidism and a negative correlation between testicular cancer and sperm concentration were subsequently found in other registries at the population level.[6] In concert with these observations, childhood TDS conditions, for example, cryptorchidism, are risk factors for TGCT and decreased spermatogenesis in adults. Isolated hypospadias but not



Predisposing gene variants
Environmental factors
Genomic aberrations
Fetal testis
Lifestyle factors
Decreased Leydig cell function
Disturbed Sertoli cell function
Decreased INSL3 production
Decreased androgen production
Impaired germ cell maturation
Cryptorchidism
Short AGD
Hypospadias
GCNIS/GBL Germ cell cancer
Decreased testosterone
Impaired spermatogenesis

Figure 115.1 Schematic representation of the concept of testicular dysgenesis syndrome (TDS). The TDS hypothesis stipulates that various male reproductive disorders are linked to impaired fetal testis development. The etiology is multifactorial and includes adverse environmental/lifestyle factors acting on genetically susceptible individuals. The cellular targets are mainly fetal Leydig and Sertoli cells, and the mechanisms involve testicular hormone insufficiency and failure of germ cell maturation, leading to different postnatal outcomes. *AGD,* Anogenital distance; *GCNIS,* germ cell neoplasia *in situ*; *GBL,* gonadoblastoma. (Modified and updated from Skakkebæk NE, Rajpert-De Meyts E, Main KM. Testicular dysgenesis syndrome: an increasingly common developmental disorder with environmental aspects, *Hum Reprod.* 2001;6:972–978.)

cryptorchidism has also been more frequent in boys born after fertility treatment and was associated with delayed pubertal onset in the Danish population.[7] A dissociation between cryptorchidism and hypospadias was also noted in New Zealand, where indigenous populations have a greater risk of cryptorchidism and TGCT than the white population, but not hypospadias, suggesting that a combination of environmental exposures and genetic background can modulate TDS manifestations in different populations.[8]

Biological Evidence

Growing biological evidence suggests that the TDS components, despite having different age of manifestation, are characterized by impaired development of the Leydig and Sertoli cells, leading to the changed hormonal microenvironment of the testis and consequently disturbed maturation of germ cells. The strongest evidence comes from studies of the early stages of TGCT, which closely resemble fetal gonocytes.[1,9] A number of studies examining the testis tissue samples from patients with TDS demonstrated focal signs of dysgenesis, including clusters of poorly developed tubules, incompletely differentiated Sertoli cells, Leydig cells nodules, and microcalcifications.[1] Similar morphological changes have been observed in experimental animals exposed to various endocrine disrupters, especially those that affect the development of the reproductive tract during the masculinization programming window.[10] Disturbed masculinization window in rodents is reflected by a shorter AGD, which is a sex-dimorphic readout of the prenatal androgen activity.[10,11] Similarly, in human patients, shorter AGD was associated at the cohort level with hypospadias, cryptorchidism, testicular cancer and poorer semen quality,[11,12,12a] supporting the syndromic nature of these conditions and their relation to the intrauterine development.[5]

The etiology of TDS is complex and likely multifactorial, but a growing number of studies identified components of TDS in subjects exposed *in utero* to environmental endocrine disrupters, for example, maternal mid-gestation serum levels of paracetamol, bisphenol A (BPA), or n-propyl paraben were associated with cryptorchidism or a shorter AGD in infants.[5,13,14] Similar studies of human prenatal exposure to phthalates were somewhere contradictory and remain inconclusive.[15,16,17]

KEY POINTS

- Testicular dysgenesis syndrome (TDS) comprises disorders linked to disturbed testis development, including cryptorchidism, testicular germ cell tumors derived from germ cell neoplasia in situ (GCNIS), some forms of hypospadias, short anogenital distance, reduced spermatogenesis, and low testosterone levels in adulthood.
- Pathogenesis of TDS is predominantly environmental, but genetic background modulates the risk.

CRYPTORCHIDISM

Cryptorchidism, or undescended testis, is one of the most common urogenital abnormalities in boys. It is mostly found isolated, but it can also occur in combination with other malformations and syndromes. An undescended testis is often indicative of some degree of testicular dysfunction, which may have long-lasting effects on especially semen quality and the risk of testicular cancer in adulthood.

Classification

Cryptorchidism is divided into a congenital and an acquired form. Synonymous terms for these two entities are *primary* and *secondary cryptorchidism.* Traditionally, cryptorchid testes are divided into nonpalpable and palpable testes, and synonyms are *undescended testis, maldescensus testis*, and *retentio testis.* During laparoscopy or surgery, a nonpalpable testis may be completely absent (vanished) or "nubbin," which refers to an atrophic remnant of tissue at the end of vessels.[18] Ideally, the precise position of the testis along its normal pathway of descent should be described in more detail: high/low abdominal testes, inguinal (canalicular), suprascrotal (superficial inguinal pouch), high scrotal (prescrotal), and scrotal. Such a distinction would ensure a better basis for future studies about the long-term impact of treatment regimens and the disease *per se* on testis function. In rare cases, the testis can be found in an ectopic position, usually in perineum, contralateral scrotum, or femoral. Unilateral cryptorchidism occurs more frequently than bilateral cryptorchidism, and in only approximately 10% of orchiopexies, the testis is nonpalpable before surgery (Fig. 115.2). Retractile testes were considered a normal variant, but this has been challenged.[19] In severely retractile cases or in children who are distressed during the physical examination, these testes may be difficult to distinguish from undescended testes. In addition, retractile testes have an increased risk to become truly cryptorchid over time, and their position needs to be monitored.[20] Testes normally descend to the lowest position during the first 3 months after birth (minipuberty) and then ascend a little again in association with changes in serum levels of reproductive hormones and IGF1.[21]

Registry data, either of congenital malformations or hospital diagnoses after orchiopexy, may differ considerably in their selection criteria from prospective standardized studies and be biased toward the more severe forms of testicular maldescent. Cumulative orchiopexy rates may also include cases of ascended testes and encompass historical changes in referral and treatment regimens. Thus reported prevalence rates may differ even within the same population.

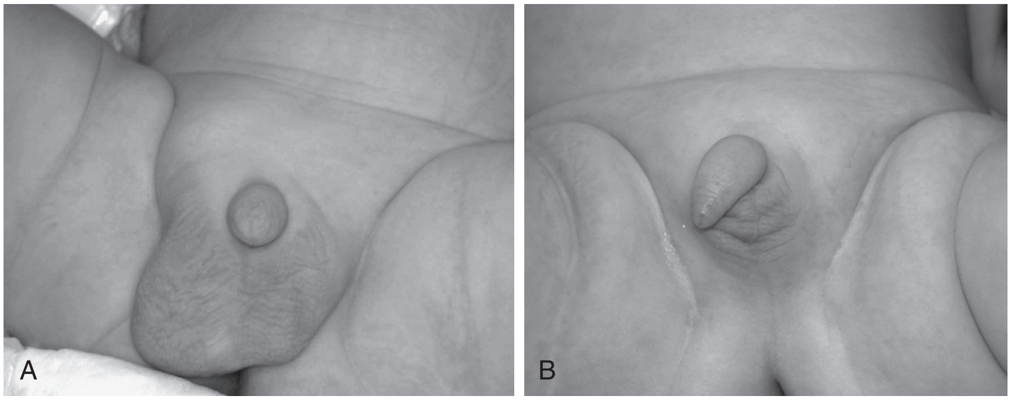


Figure 115.2 Infants with unilateral (**A**) and bilateral (**B**) cryptorchidism. It is important that the diagnosis is not based on the visual inspection but by a careful palpation of scrotum in warm and comfortable conditions.

The clinical examination can on occasion be technically difficult. It requires an experienced observer, warm and relaxed conditions, and may need to be repeated if the child is upset. Examination should be done not only in the supine position but also cross-legged or upright before a definite diagnosis is made. An experienced examiner may have a higher sensitivity for locating an undescended testis than ultrasound or other imaging techniques. The American Urological Association guidelines recommend withholding of ultrasound or other imaging before referral to a pediatric surgeon.[20] The testis is brought into the lowest possible position along its normal pathway of descent by gentle, not forced, traction and should remain there for a while after exhaustion of the cremaster reflex. An asymmetric or hypoplastic scrotum may further suggest unilateral or bilateral cryptorchidism, respectively.

The position of the testis during infancy and childhood is not necessarily stationary, and there is a consensus that boys should be examined repetitively as part of their standard health care program. A significant proportion of the testes in congenital cryptorchidism descend spontaneously during the first months of life.[22] Testes, scrotally placed at birth or retractile, can ascend during infancy and childhood. The acquired undescended testis is more frequent than previously thought, but the etiology and consequences are yet unclear.[23]

Embryology

The development of the testis and its descent from the abdomen into the scrotum is a highly complex process, with numerous genetic and hormonal factors involved.[24] Testicular descent in humans occurs in two phases, the transabdominal phase and the inguinoscrotal phase, which are usually completed around gestational weeks 15 and 35, respectively. During the first phase, the testis is anchored at the internal inguinal ring by enlargement of the gubernaculum. In rodents, the masculinization of the gubernaculum is highly dependent on insulin-like hormone 3 (INSL3), secreted by Leydig cells, and INSL3 receptor, leucine-rich repeat-containing G-protein–coupled receptor (also known as LGR8, RXFP2), whereas mutations of these genes in humans have only rarely been reported in large series of patients with cryptorchidism. The regression of the cranial suspensory ligament and the second phase of descent are highly dependent on androgens. The inguinoscrotal descent is often compromised in hormonal disorders of the pituitary–gonadal axis or steroidogenesis and androgen receptor mutations. The role of the genitofemoral nerve (GFN) and its neurotransmitter, calcitonin gene-related peptide (CGRP), in the inguinoscrotal phase of descent is less well established in humans than in rodents. However, the high prevalence of cryptorchidism in spina bifida and caudal regression syndromes indicates that GFN also plays a role in testis descent in humans.

Etiology
